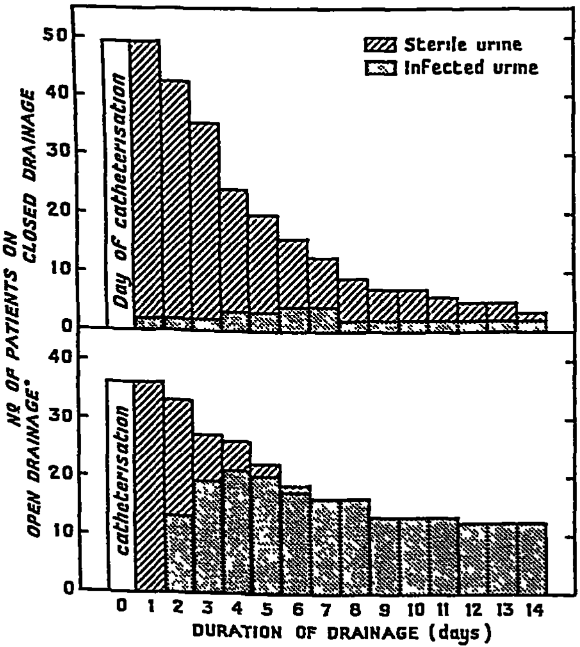
On open drainage infection usually developed quickly, whilst on closed drainage survival without infection was the rule even when the drainage was continued for many days (fig 2) Of the 5 patients on closed drainage who did become infected, 2 developed their infections within eighteen hours of catheterisation, probably as a result of the insertion of the catheter and not of subsequent retrograde infection. None of the 10 patients whose closed drainage was inadvertently disconnected survived infection for more than two days afterwards



* Includes 10 patients whose closed drainage was inadvertently disconnected

Fig 2—Urinary infection following insertion of indwelling catheters, in relation to method of draining the bladder

Nature of Infection

In our hospitals, most urinary infections after prostate operations are caused by "hospital organisms" with abnormal antibiotic sensitivities (Gillespie 1956) Similar organisms caused infection in the cases described above (see table II)

Discussion

In all catheter drainage systems, after the initial catheterisation has been achieved without infection the chief dangers are contamination of the end of the catheter by disconnection, and by bacteria conveyed by air bubbles which rise up the drainage tube from the open end This latter hazard can be avoided by using a closed system with an antiseptic fluid seal in the collecting bottle

TABLE II—ANTIBIOTIC RESISTANCE OF BACTERIA IN INFECTIONS COMPLICATING CATHETER DRAINAGE OF ACUTE RETENTION OF URINE

Organisms	Total infections	Antibiotic sensitivities
Streptococcus fæcalis	7	
Staph aureus	6	1 sensitive and 5 resistant to penicillin 4 also resistant to sulphonamides, streptomycin, and other antibiotics
Coliform bacilli	8	All resistant to sulphonamides and streptomycin
Proteus species	10	All resistant to sulphonamides and streptomycin 9 also resistant to other antibiotics
Pseudomonas pyocyanea	2	1 sensitive and 1 resistant to sulphonamides, streptomycin, chloramphenicol, and oxytetracycline
Other gram-negative bacilli	4	All resistant to sulphonamides, streptomycin, and oxytetracycline
Total	37	28 organisms with abnormal antibiotic resistance

Infections by *Staph albus* are not included

So many complications of prostate operations are due to infection that every effort should be made to prevent infection both before and after operation Bacteria which are allowed to invade the urinary tract are potential causes of lethal bacteræmic shock, septicæmia, or pyelonephritis (Ezzo and Knight 1957, Slade 1958, Miller et al 1958) In recent years, emergency prostatectomy has been advocated as the best treatment for acute retention because it avoids preliminary catheter drainage with its inevitable risk of infection In our experience emergency prostatectomy for acute retention can produce excellent results because of the sterile operation field which can be maintained, but there is also little doubt that if one can avoid infection by other means and so enable the operation to be done at a reasonable hour with the same chance of maintaining sterile urine, one may also avoid other hazards incidental to emergency surgery performed at a late hour of night The ease with which these cases become infected is demonstrated by the results in the group in which the catheter was disconnected To be effective, therefore, the drainage system must be kept closed for the whole period of drainage

The same system could be used for continuous drainage of the bladder in other conditions

Summary

A controlled trial of a simple closed aseptic drainage apparatus for use after catheterisation for acute retention of urine is described

The apparatus can be cleaned, sterilised, and kept ready for use in the ward

Its use in the treatment of patients with acute retention of urine enabled sterility of the urine to be maintained in the great majority of cases, until they came to operation With open drainage, most patients quickly became infected

We thank the board of governors of the United Bristol Hospitals and the management committee of Southmead General Hospital for grants towards the cost of this research, and the ward sisters for their enthusiastic assistance

THE DIURETIC EFFECT OF SPIROLACTONE SC-9420 IN A CASE OF SECONDARY ALDOSTERONISM

From the Department of Internal Medicine of the University of Amsterdam

Kagawa et al (1957) and Liddle et al (1957) reported that synthetic steroids—the spirolactones designated SC-5233 and SC-8109—block the renal effects of aldosterone and deoxycortone (desoxycorticosterone) in adrenalectomised animals and patients with adrenal insufficiency In the absence of sodium-retaining hormones the drug had no effect

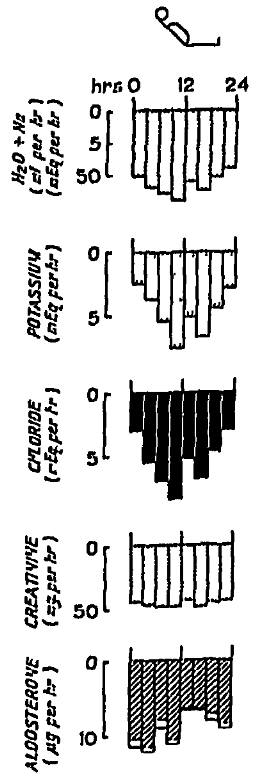

Fig 2—Diurnal excretory rhythm Experimental conditions as described under fig 3 Sodium output was less than 1 mEq per day, too small to be depicted Both results of duplicate determinations of aldosterone are given

The magnitude of the response was directly related to the dose of steroidal spirolactone and inversely related to the dose of sodium-retaining substances given. Therefore the blocking effect was thought to result from competitive inhibition, probably at the level of the renal tubules

When a high urinary output of aldosterone was induced in normal subjects by feeding a low-sodium diet, spirolactones had the same effect as in patients with Addison's disease who were receiving deoxycortone The drugs were also given to a number of patients with œdema due to congestive heart-failure, who, as was observed by Deming and Luetscher (1950), excrete large amounts of sodium-retaining substances in the urine Most cases responded with increase in sodium and water excretion and no change or reduction in the excretion of potassium The observed reduction in the excretion of titratable acid and ammonia is regarded as further evidence that steroidal spirolactones act as specific aldosterone inhibitors (Liddle 1958)

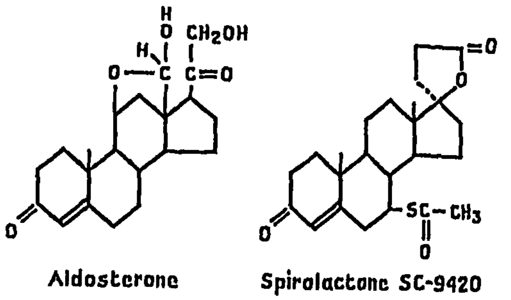

Fig 1—Chemical formulæ of aldosterone and the steroidal spirolactone SC-9420

Kerr et al (1958) gave SC-8109 by intramuscular injection to three patients with liver cirrhosis and ascites. A sodium and water diuresis occurred in two; potassium output and body-weight did not change

Unfortunately these spirolactones have to be given parenterally in microcrystalline suspensions or oily solutions, the effective oral dose being 30–60 times the parenteral dose

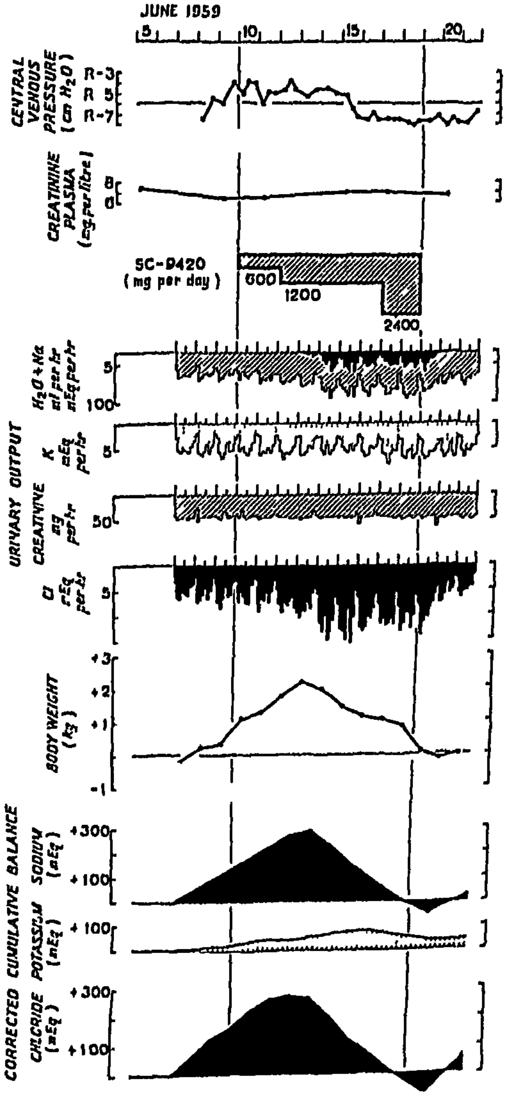

Fig 3—Effect of SC-9420 During the observation period the patient remained in bed and received 3-hourly equal supplies of food providing 1710 calories, 57 mEq Na, and 85 mEq K daily, and drugs making a total of 30 g urea, 48 mEq KCl, 64 mEq NH_4Cl, 0 4 mg digoxine, 10 mg thyroid, and 4 µg triiodothyronine daily

We have used a new spirolactone SC-9420 (fig. 1) on which no clinical data have hitherto been available It

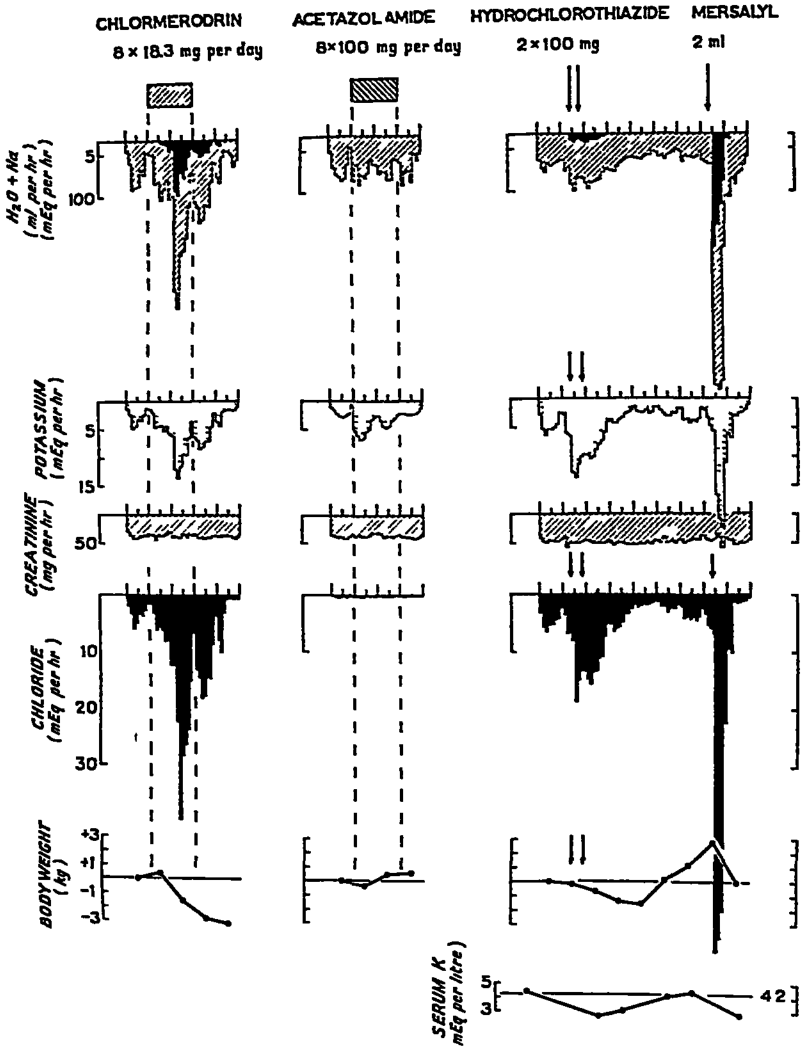

Fig 4—The effect of four diuretics Same legend as in fig 2. CaCl$_2$ was given instead of NH$_4$Cl during the treatment with chlormerodrin and no KCl and NH$_4$Cl was given during the treatment with acetazolamide

can be given by mouth. The makers claim that its dose-response relation is better than that of the earlier spirolactones We tested it in a proven case of secondary aldosteronism and compared the pattern of diuresis with that induced by other diuretics

Investigation

The patient, a highly cooperative man of 29, has severe chronic heart-failure due to rheumatic mitral stenosis and incompetence with auricular fibrillation.

Previous History

He has been under our close observation for 6 years Treatment has been by a salt-free diet, digoxin, and mersalyl, with sufficient amounts of ammonium chloride, several times urea has had to be administered for many weeks to combat hyponatræmia Gradual deterioration of cardiac function led in 1953 to inefficacy of even large doses of mersalyl This necessitated a total suppression of thyroid function with ^{131}I, after which the mersalyl became effective again. He is on a subliminal supply of thyroid powder, and his intake of salt and water is rigidly restricted. Moreover, he still needs ammonium chloride and injections of mersalyl to keep him free from œdema. For 6 years he has not excreted any sodium except on the days that mercurial diuretics were given Renal function is unimpaired On rigid fluid restriction urine osmolarity rises to 1200 milliosmol per litre Creatinine-clearance is about 120 ml per minute (more than 50 determinations)

Unfortunately increasing symptoms of hypersensitivity to mersalyl have developed. We have therefore tried the effect of other diuretics on water and electrolyte excretion under the rigorously standardised conditions described in previous papers (Borst and de Vries 1950, Borst 1954)

Observations without Spirolactone

The patient was kept in bed on an intake of 57 mEq daily The urine was collected in 3-hour periods and analysed for sodium, chloride, potassium, and creatinine Under these conditions even small changes in the pattern of diuresis can be distinguished. Body-weight and arterial and central venous pressure (method of Borst and Molhuysen 1952) were recorded daily, serum electrolytes, hæmoglobin, and plasma creatinine at regular intervals A corrected cumulative balance of sodium, potassium, and chloride was calculated as described by Molhuysen et al. (1950)

Using the method of Moolenaar (1957, 1958) we found a urinary excretion of 205-310 microgrammes aldosterone per day, whereas the normal values for persons on a normal salt intake are 3–13 microgrammes During one of the experiments the patient excreted on a control day more aldosterone in a 3-hour period than normal persons excrete during the day The highest aldosterone output was between midnight and noon (fig 2)

Effects of Spirolactone

Fig 3 shows that in the control period no sodium was excreted The cumulative sodium balance was positive, and the body-weight and central venous pressure rose After the dosage of spirolactone had been increased to 1200 mg per day sodium output started, and it is noteworthy that the excretion pattern of sodium followed the normal diurnal rhythm The cumulative sodium balance changed from about +300 mEq to zero Chloride output had the same pattern The influence on the potassium excretion was insignificant However in the period when the sodium balance was negative the (corrected) cumulative potassium balance showed a slight positive trend The excretion of creatinine and the creatinine-clearance were unaffected. Increasing the dose of SC–9420 to 2400 mg per day for 2 days had no additional effect

With the small supply of SC–9420 available the treatment could not be continued After it was abruptly stopped the sodium output took at leat 36 hours to return to the zero level

The levels of serum electrolytes remained constant during the experiment, nor did the arterial pressure and pulse-rate change The body-weight and the central venous pressure rose and fell parallel with the sodium balance At the peak of retention the patient was uncomfortable and dyspnœic, and he benefited greatly from the diuretic effect of the spirolactone. The only side-effect noted was slight drowsiness

The excretion pattern of aldosterone and other adrenocortical steroids during the trial with sc-9420 could not be studied, because immediately after the beginning of the treatment at least two oxidation products of the steroidal spirolactone were excreted in the urine and interfered with the chromatographic separation of aldosterone and the Zimmermann colour reaction.

Fig 4 shows the renal response to several diuretics in the same patient under similar conditions It is clear that the effect of spirolactone sc–9420 differs from that of the diuretics quantitatively and qualitatively

Mersalyl provoked a large diuresis comprising water, sodium, chlorides, and potassium the effect started at once and lasted 24 hours Chlormerodrin, a mercury compound for oral use, showed the same pattern but the effect lasted longer The only effect of acetazolamide (' Diamox ') was an increased excretion of potassium. Hydrochlorothiazide in high dosage gave a small sodium output, yet the sodium balance remained positive There was a very marked rise in the excretion of potassium In spite of the 85 mEq potassium in the diet and the additional supply of 48 mEq potassium per day, the cumulative potassium balance became negative (balances not presented in fig 4) and the serum-potassium level dropped from 4 3 to 2 75 mEq per litre The diuresis was followed by a compensatory retention of potassium

Although the diuretic effect of sc–9420 is weaker than that of mersalyl, the results obtained in a short experiment suggest that the spirolactone by " selective chemical adrenalectomy " can also keep this patient in circulatory and electrolyte equilibrium, which non-mercurial diuretics could not achieve

Summary

The new spirolactone sc–9420 was tested under standardised conditions in a patient with heart-failure, who excreted large amounts of aldosterone in his urine and who for 6 years had not excreted sodium in the urine except when mercurial diuretics were given The spirolactone induced an appreciable sodium output, while the potassium output remained almost constant The characteristic excretion pattern could be distinguished from that produced with various other diuretics in the same patient Side-effects were unimportant

sc-9420 used in this trial was supplied by Messrs G D Searle We thank Prof A Querido (Leiden) for his instructions and help with the aldosterone determinations

"On admission he had been asked if his diet was normal and had replied yes After some time one of the physicians asked what exactly had he been eating, and when this question was put, the patient said he had been eating little more than bread, margarine and treacle during the last three years In asking the patient if his diet was normal, the questioner had wanted to know if his diet was suitable to maintain health, in saying that his diet was normal the patient had wanted to say that there had been no recent change from his usual diet. This is an example where the questioner failed to obtain the information he required because different people attributed alternative meanings to the same word "—M L JOHNSON ABERCROMBIE, *The Anatomy of Judgment*, p 106 London Hutchinson 1960

THE NATRIURETIC ACTION OF HEPARIN AND SOME RELATED SUBSTANCES [*]

R J A F M SCHLATMANN

HEAD OF THE CLINICAL LABORATORY
C L H MAJOOR
M D
PROFESSOR OF MEDICINE
From the Department of Medicine of St Radboud Hospital, University of Nijmegen

IN an earlier paper (Majoor et al 1957) we showed that heparin has a diuretic action in patients with œdema of varied ætiology Moreover, in a man with coronary insufficiency without œdema or any other signs of heart-failure, sodium balance became distinctly negative and potassium balance slightly positive during intravenous heparin therapy The diuretic effect never appeared until after 36 hours of treatment, and did not reach a maximum until 3 days later When the heparin injections were discontinued, sodium excretion took about two days to return to its basal level In one patient potassium excretion was found to be increased in the first few days after stopping the drug The combination of natriuresis and potassium retention suggested that heparin might suppress the adrenal cortical function

Coumarin drugs did not increase sodium excretion in any of these patients

Since 1957 we have accumulated further evidence that heparin is a diuretic with a characteristic excretion pattern for sodium, often accompanied by slight potassium retention, and that it acts both in patients with œdema and in healthy persons (Majoor et al 1960) In this paper we report on the diuretic activity of the semisynthetic heparin congeners 'Thrombocid'[†] and Ro1-8307 [‡] Thrombocid is an anticoagulant used in many German clinics Ro1-8307 is a heparinoid said to have low anticoagulant activity with relatively distinct clearing properties (Studer et al 1956, Reber et al 1959) Table I

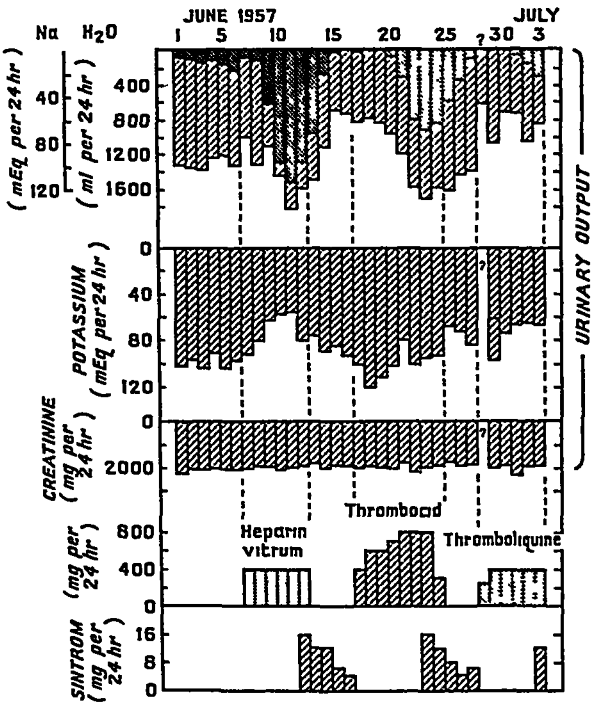

Fig 1—Diuretic response to two commercially available heparins and thrombocid in patient A.

shows some chemical and physiological properties of the three polysaccharide sulphates used.

Material and Methods

The diuretic action of heparin and the two heparinoids was studied in six patients—three with thrombosis of the legs, one with thrombosis of the brachial vein, one convalescent from bronchopneumonia, and one with a nephrotic syndrome. Three or four intravenous injections were given each day, for 5–8 days in most patients. The daily dose for patients A, B, D, and E is indicated in the figs 1–4. C and F received 300 mg of heparin daily for 4–6 days. During a second period of investigation increasing amounts of Ro1-8307 were given (100–450 mg daily) to a total of 3000 mg over 15 consecutive days in patient C and 3000 mg over 8 days in patient F.

As heparin and heparinoids are sodium salts of strong acids, we have determined the sodium content of the preparations used. We found 0·27–0·31 mEq Na+ per ml for all three drugs (1 ml. contains 50 mg of the drug). Daily sodium intake was increased in this way with 1·5–2·0 mEq per 24 hours during heparin or Ro1-8307 therapy. As thrombocid was given in doses up to 800 mg per 24 hours, these patients received a sodium increment of at most 5 mEq per 24 hours. It is clear from figs 1–4 and table II that these small amounts of sodium could not be the cause of the enhanced sodium output found in our patients.

Diets

Two kinds of diets were supplied to the patients.

(*a*) The 24 hours were divided into eight periods. At the beginning of each 3-hour period the patients drank a constant amount of milk and water, in most experiments supplemented by a fixed quantity of canned fruit-juice of one consignment, some biscuits, and in some cases a few grammes of cheese, always of the same lot. In this way the intake of fluid, electrolytes, and calories was kept constant. At the end of each period urine was collected and great care was taken to avoid loss. During the observation the patients remained recumbent. This technique of examination was described by Borst and de Vries (1950).

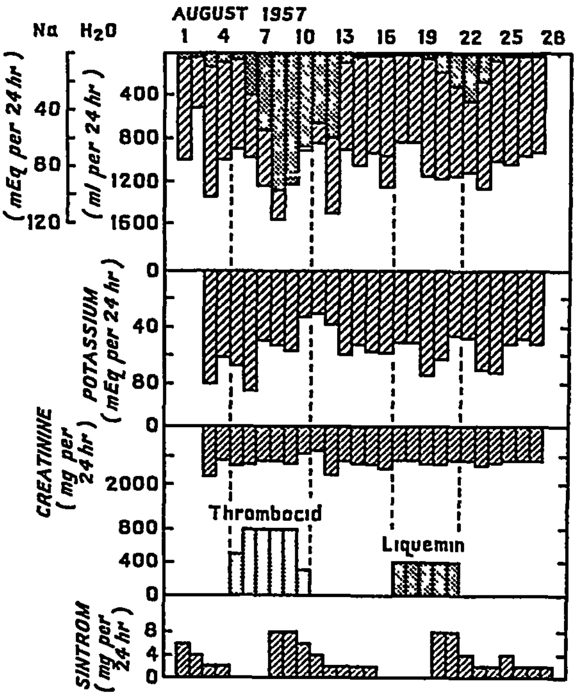

Fig 2—Diuretic response to thrombocid and the heparin liquemin in patient B.

(*b*) All foods and drinks were weighed and measured, and the daily ration was kept constant. The sodium content of these diets was low (about 10–20 mEq per 24 hours). To keep the potassium intake constant, canned vegetables of one kind and the same brand were used. Three meals were given each day. Urine was collected over 24-hour periods. All patients were weighed daily before breakfast.

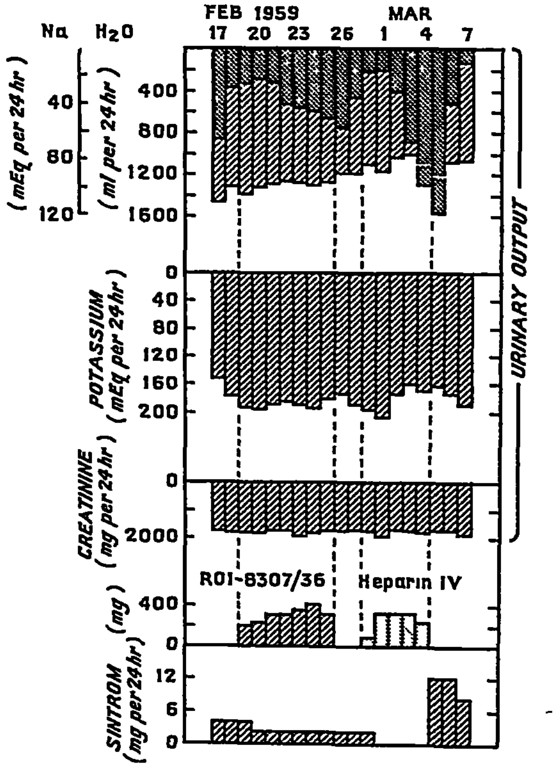

Fig 3—Diuretic response to Ro1-8307/36 and heparin in patient D.

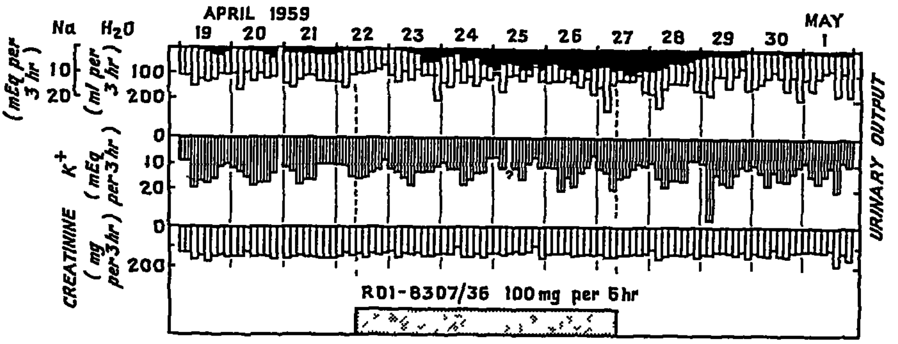

Fig 4—Diuretic response to Rol-8307/36 in patient E

Laboratory Methods

Sodium and potassium were determined by flame photometer To check the accuracy of urine collections creatinine was determined in all samples, using the alkaline picrate method For purposes of comparison the mean daily urinary excretion of water, sodium, potassium, and creatinine was calculated over short periods before, during, and after administration of the drug used To represent the period of treatment, the days with a maximal urinary sodium output were selected in most cases this was the 3rd to 5th day of drug administration To represent the period after drug administration, we chose the first days when pre-treatment levels of sodium excretion were regained—often the 3rd to 5th day after withholding heparin or heparinoids

Results are shown in table II and the figs 1–4

Results

All patients responded to heparin or heparinoids by an increase of urinary sodium excretion The pattern of this response is seen in figs 1–4 Sodium excretion did not increase until after 36 hours of therapy, and was maximal after 3–5 days At the same time potassium excretion decreased slightly or remained constant. For 2–3 days after withdrawal of the drugs a slight increase in potassium excretion was noted in some cases, usually associated with a urinary sodium output lower than it was before treatment

Compared on a weight basis, thrombocid and Rol-8307 seem to be less potent diuretics than heparin

Discussion

As most of these results were obtained in patients with thrombosis, the natriuretic action of heparin might seem attributable to improvement of the circulation, caused by the action of heparin on the thrombotic process and the absorption of local œdema Against this explanation are the following facts

1 Coumarin drugs did not increase sodium excretion in any of our patients

2 Heparin had a distinct effect on sodium excretion in patients E and F who had no thrombosis

3 Rol-8307 has almost no influence on coagulation, but shares the natriuretic properties of heparin

4 During heparin therapy, slight retention of potassium was seen in most patients Borst (1954) has shown that circulatory diuresis is usually attended by potassium excretion

A diuretic pattern consisting in elimination of fairly large amounts of sodium (and chloride) with moderate amounts of water, and retention of potassium, points to the distal renal tubules as the site of action This excretion pattern is similar to that found in Addison's disease and can be reproduced by administration of amphenone (Renold et al 1957, Thorn et al 1957) and spirolactones (Liddle 1957) Hence it seems possible that heparin and the heparinoids (or their metabolites ?) act by reducing the output of aldosterone, as amphenone does, by blocking steroid action in the kidney, as suggested for the spirolactones, or by accelerating the destruction or

* i e , number of days used for computation of mean outputs

elimination of aldosterone These possibilities are being investigated (Cejka et al 1960)

In sharp contrast to the action of mercurials, acetazolamide, and chlorothiazides, the diuretic action of heparin or the heparinoids never became apparent during the first 36 hours of therapy and never stopped within 48 hours of terminating intravenous administration Though a late natriuretic response of the same type has sometimes been reported after amphenone and less definitely after spirolactone administration, in other experiments an immediate response was found (Renold et al 1957, Thorn et al 1957, Liddle 1957, 1958, Ross and Bethune 1959) As heparin and related substances without exception caused a delayed type of diuresis, at present they seem to occupy a unique position among drugs with diuretic action

It is interesting that polysaccharide sulphates so different in source, composition, and molecular weight as heparin, thrombocid, and Ro1-8307, should have diuretic actions of about the same magnitude and of exactly the same type It is possible, too, that the dextran sulphate 'Dexulate' shares this diuretic action, since Jeavons et al in 1956 observed a patient with venous thrombosis associated with pulmonary embolism, who lost 8 5 kg in weight during the first 6 days of dexulate treatment Rapid disappearance of œdema in patients with thrombophlebitis during dexulate administration was also observed by Donzelot et al (1955)

Our own observations suggest that the natriuretic action of the heparinoid Ro1-8307 deserves further study, because this drug, in the dosage used, is almost devoid of anticoagulant action (Studer et al 1956, Majoor et al 1960) Studer et al (1956) administered Ro1-8307 as a clearing agent to nineteen patients for 8 weeks, without toxic manifestations But their dose of 100 mg three times weekly was far lower than that needed for diuretic action

In the short-term experiments we describe here, with daily doses up to 450 mg, the drug was tolerated without untoward effect by all patients except F—a girl with a nephrotic syndrome who vomited twice on the last day of drug administration With growing experience with the intravenous and intramuscular administration of Ro1-8307, both in our department and in the department of internal medicine in Amsterdam (Cejka et al 1960), vomiting and diarrhœa have been noted in only three other patients, all of whom had membranous glomerulonephritis with severe albuminuria In two of these, who vomited shortly after their first dose of 100 mg intravenously, treatment was not continued In the third patient, who was in a remission after prednisone treatment, vomiting and diarrhœa started on the 9th day of therapy, when 4000 mg of the drug had been given intramuscularly Toxic manifestations subsided immediately when injections were stopped

These observations show that a careful watch for drug intolerance should be kept whenever long-term administration of Ro1-8307 in relatively large amounts is used for treating intractable retention of sodium and water

Summary

The diuretic action of heparin was compared with that of the heparin congeners 'Thrombocid' and Ro1-8307 Each drug produced natriuresis and often slight potassium retention The renal excretion pattern following administration of these polysaccharide sulphates is very similar to that seen in Addison's disease or after administration of amphenone and spirolactones This points to their having an inhibitory influence on the secretion or action of aldosterone

Preliminary Communication

EFFECT OF HEPARINOID AND SPIROLACTONE ON THE RENAL EXCRETION OF SODIUM AND ALDOSTERONE

Two types of drugs seem to reduce the influence of the adrenal cortex on the function of the renal tubules Heparin[1] and heparinoids[2] probably act by reducing the secretion of aldosterone by the adrenal Spirolactones block the effect of aldosterone, deoxycortone, and related substances by competitive inhibition[3]

We have studied the effect of both types of drugs, given separately and simultaneously, on the urinary output of sodium and aldosterone This report concerns our first three patients

PATIENT 1 has cardiac failure with secondary aldosteronism He was on a strictly standardised diet providing 57 mEq of sodium daily Data on the effect of spirolactone are presented in a previous paper[4] Intravenous injections of heparin (100 mg four times daily) induced a steep fall in aldosterone output Sodium excretion started, but was insufficient to induce a negative sodium balance before severe signs and symptoms of congestive failure obliged us to stop the experiment Moreover, the patient had several large subcutaneous hæmorrhages

PATIENT 2, a man of 48, with hypertension, was on a salt-poor diet His weight was constant, while the daily sodium output in his urine ranged from 28 to 10 mEq (average 17 mEq) Spirolactone SC-9420, 200 mg by mouth four times a day, immediately increased the sodium excretion (fig 1) In the following week urinary sodium output decreased despite continued treatment Doubling the dosage did not much increase sodium excretion Owing to the presence of spirolactone metabolites, determination of aldosterone in the urine was impossible When the determinations could be resumed, the aldosterone output was higher than before treatment Heparinoid Ro1-8307, 800 mg given intramuscularly twice daily as a depot, was followed by a fall in aldosterone excretion and by a gradual increase in urinary sodium output Addition of spirolactone hardly increased the sodium output, nor did addition of 0 5 g chlorothiazide daily The patient, however, was by this time in a state of salt depletion, the blood-sodium level having fallen to 128 mEq per litre

Treatment with salt restriction and diuretics—of which mersalyl had most effect—resulted in a slow decrease of the central venous pressure, but this remained 2–4 cm above the normal level. The œdema diminished as shown by the loss of body-weight. After the loss of œdema she developed a voracious appetite and could hardly be satisfied with 1900 calories. The intake of salt was 17 mEq per day. In spite of treatment with 0·5 g chlorothiazide daily, no sodium was excreted in the urine. Body-weight and central venous pressure gradually increased. In this period the excretion of aldosterone in the urine was 40–60 µg per day (see fig 3). During intramuscular injection of Rol-8307 (at first 100 mg and later 200 mg four times a day) the excretion of aldosterone decreased to 4 µg daily. Sodium excretion increased. On the thirteenth day of heparinoid treatment, while sodium excretion was on a level, sc-9420 (four doses of 200 mg) was given orally in addition. This 800 mg prompted a massive excretion of sodium in the urine, continuing at least five days. Central venous pressure and body-weight rapidly decreased. The sodium output exceeded and markedly outlasted that induced by mersalyl. When the treatment with

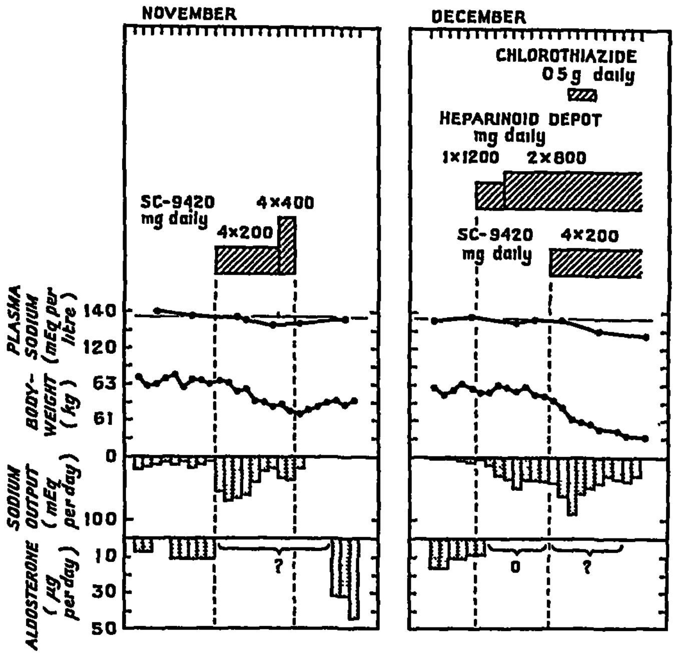

Fig 1 (patient 2)—Renal aldosterone and sodium excretion following treatment with spirolactone and heparinoid separately and simultaneously

PATIENT 3, a married woman born in 1902, has had congestive heart-failure since 1952.

In 1955 she was operated upon for concretio pericardii (Professor Boerema, Amsterdam) after which kymography showed an increase in cardiac pulsations but the congestive heart-failure did not improve. For four years she remained in fairly good condition. She was on a salt-poor diet and received 2 ml mersalyl every fifth day, together with an adequate amount of ammonium chloride. In spite of this regimen, in the spring of 1959, œdema increased and in August she was admitted to the Binnengasthuis. The heart-failure was severe. She had massive œdema and a very high central venous pressure, which amounted to 3 cm above the level of the sternal angle (see fig 2).

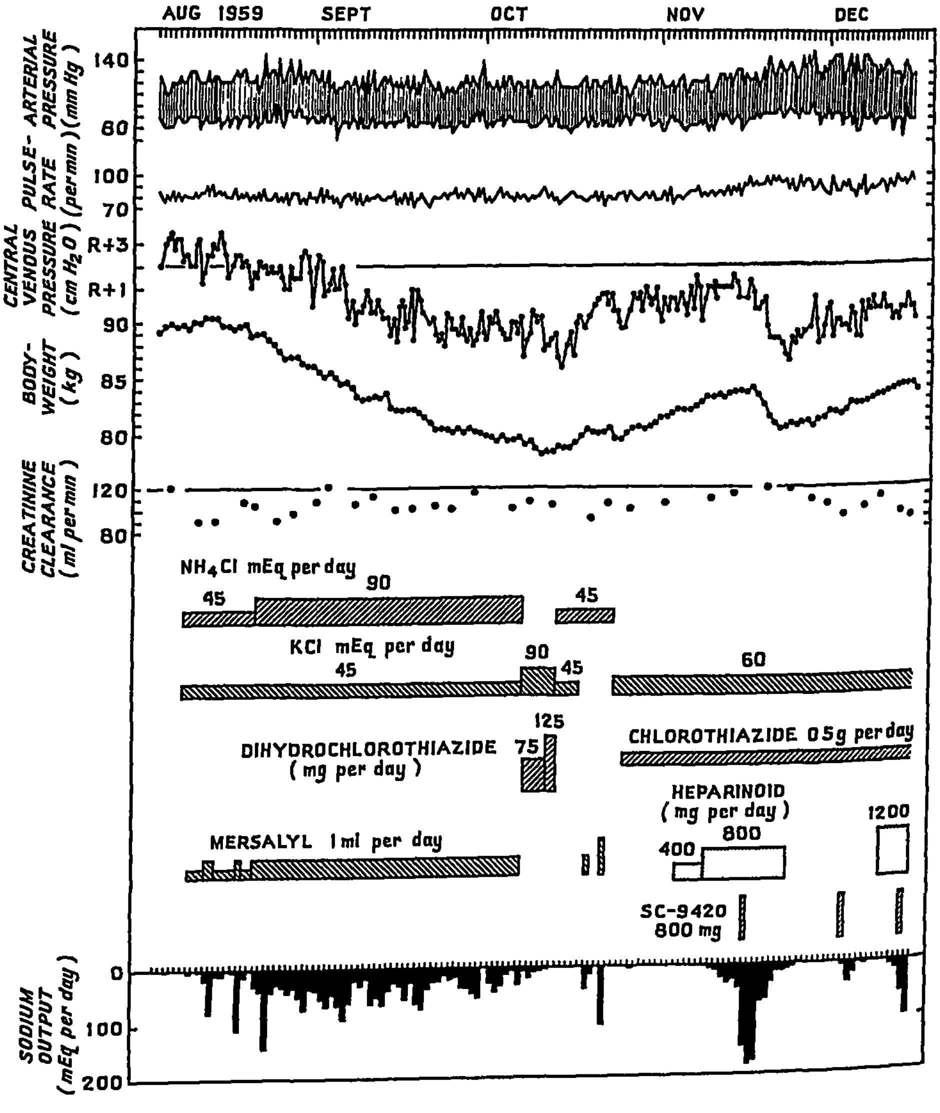

Fig 2 (patient 3)—Comparison of the natriuretic effect of mersalyl and the chlorothiazides with that of heparinoid and spirolactone administered separately and simultaneously. The blood-sodium level (not presented) was almost constant.

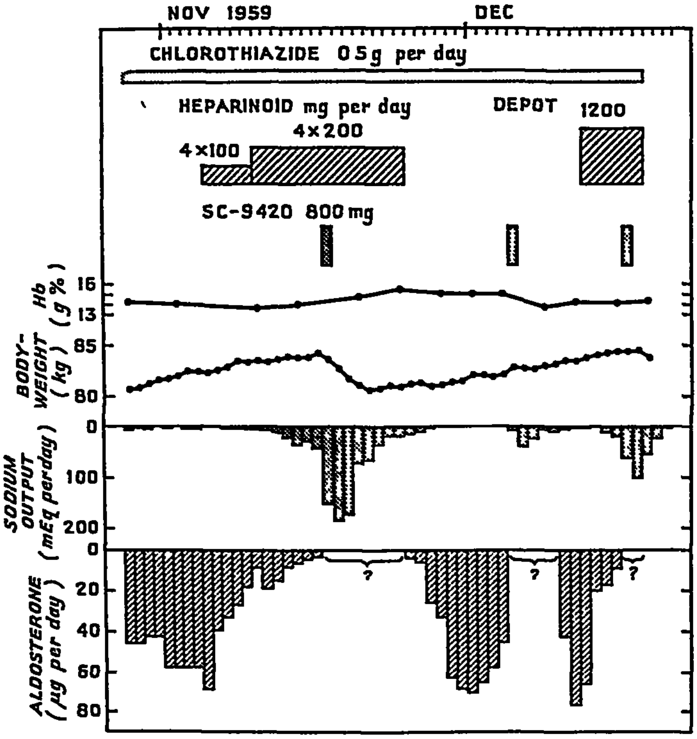

Fig 3 (patient 3)—Renal aldosterone and sodium excretion following treatment with spirolactone and heparinoid separately and simultaneously

heparinoids was discontinued, the excretion of aldosterone increased to control levels in four days Without heparinoid, administration of the same dose of spirolactone for one day resulted in a small excretion of sodium lasting four days Resumption of heparinoid administration, this time with 1200 mg of a depot preparation in one intramuscular injection daily, met with the same type of response Addition of 800 mg spirolactone again initiated a further appreciable rise in sodium excretion

The patient left hospital on Dec. 18 in a good condition She continued collecting the twenty-four hours' urine That day and the two days thereafter she had no treatment The last dose of chlorothiazide was given on the 17th at 6 A M Nonetheless the sodium output on Dec. 18 was still high and then declined rapidly The blood-sodium level was almost constant during the whole period of observation, and the creatinine output in the urine fluctuated only insignificantly

In this case of secondary aldosteronism the effect of the combined treatment with sc-9420 and Ro1-8307 on sodium excretion is much greater than the sum of the effects of the two drugs separately Though the influence of aldosterone on tubular reabsorption of sodium must have been reduced to a very low level, the peak sodium excretion was much lower than that present in normal persons on a high sodium intake or in some patients with cardiac failure during a good response to digitalis Therefore we conclude that the sodium retention was caused partly by other factors of the same importance as aldosterone

The creatinine clearance was slightly higher during the period of greatest sodium excretion but stayed on the same level for some days, during which sodium was again retained During the second sodium diuresis the clearance was on a lower level It is highly improbable that sodium excretion in this case was influenced by the alterations in the creatinine clearance

No side-effects of the heparinoid were noticed, coagulation-time was normal and signs of hæmorrhagic tendency were absent However, some of the patients with nephrotic œdema, who were treated with the heparinoid Ro1-8307 in the University Hospital at Nijmegen showed signs and symptoms that may be attributed to a toxic effect of the drug [2]

SUMMARY AND CONCLUSIONS

In three patients on restricted salt intake (two of whom had secondary aldosteronism) administration of heparin and heparinoid Ro1-8307 was followed by a gradual decrease in urinary aldosterone to levels found in normal subjects on an unrestricted salt intake Sodium output increased, the changes in sodium output not being related to changes in creatinine clearance

In a patient treated with 1200 mg heparinoid and 500 mg chlorothiazide daily, 800 mg of spirolactone given on one day increased the sodium output for five days, the effect being far more than additive The sodium output greatly surpassed that induced by mersalyl and the chlorothiazides in high dosage On the other hand, it was less than that seen in normal persons on a high sodium diet

Ro1-8307 was supplied by Hoffmann-La Roche Laboratories, Basle, and sc-9420 by G D Searle & Co , Chicago

Evolution of Viruses

A meeting was held in London on Jan 21

Prof C D **Darlington** said that a change of host (as in myxomatosis when introduced into Australian rabbits, or measles when introduced into Polynesia) often means an increase of virulence—after which there is a sharp decline both in the virulence of the parasite and in the susceptibility of the host, apparently through natural selection. Transplantation by an arthropod vector can transform the character of a virus, and the question arises whether the vector finds the virus ready-made as an infectious organism. A nucleoprotein propagating itself normally in one organism may become a virus in another something transmitted by the cytoplasm in heredity, or generated by the cell, becomes communicable by infection On the other hand a virus can become a harmless nucleoprotein or become latent, doing no harm to its host Latency is imagined to have existed in all situations where a new virus has arisen where no virus was known before

Mr P F **Mattingly** pointed out that though each virus is isolated in the tissues of the host, it has like other organisms an ecology of its own, independent of adventitious transfer to man or occurrence in atypical hosts or vectors At present the requirements for establishing a mosquito-borne virus are warm-blooded vertebrates, angiospermous plants, and blood-sucking mosquitoes The first two evolved together in the Tertiary period, and the viruses and mosquito vectors probably evolved with them. The fact that mammalian malaria parasites are transmitted by anophelines, and bird-malaria parasites (in the laboratory and therefore presumably in Nature) by culicines, suggests that anophelines evolved as mammal feeders and culicines (at least in part) as bird feeders The basic *maintenance cycles of mosquito-borne viruses* involve culicines only (except for the subgenus kerteszia), and this suggests that the primitive viruses of this group were bird viruses Aedes-borne viruses are confined to the tropics, culex-borne viruses are found in the subtropics, and tick-borne viruses in the northern steppes The explanation seems to be that aedes hibernate and æstivate in the egg, and culex hibernate and æstivate as adults, which permits them to withstand the severe conditions of the subtropics Further north, where only the resistant egg will serve for hibernation, aedes are the dominant mosquitoes, but they do not pass on the viruses through the egg, and are therefore unsuitable for maintaining them, and the mosquito-borne viruses are replaced by tick-borne viruses The West Nile virus is probably the most primitive of the group-B viruses and the picture would be of invasion from the subtropical savannah northwards to steppes and tick vectors, and southward to tropical habitats and aedes vectors But possibly the Russian spring-summer viruses are the most primitive, and if this were so the picture might be simpler and more coherent.

Dr C E **GORDON SMITH**, taking up the evolution of arborvirus diseases, showed a list of the arborviruses known to cause diseases in man, but he noted that progress may occur from a virus infecting only an arthropod and transmitted through the egg, to a virus transmitted from arthropods to an animal other than man, thence by a second arthropod to man, and finally between man and man through this secondary vector Hence there may be many arborviruses still " in search of disease " The factors influencing the maintenance of arborviruses in Nature are extremely complex and are often strongly affected by human activity—e g, irrigation, insecticides, artificial immunisation, or the effect of sanitation on the age of the population The viruses themselves fall into several groups, but changes in virulence and antigenic structure, and phase variations, are all observed and are related to mutations Selection pressures occur in the vertebrate and arthropod hosts

Dr C H **ANDREWES** remarked that the viruses are probably very old in evolutionary history, they probably evolved along with their hosts and vectors, and the tick-borne viruses may be the oldest Their evolution may be affected by short-term factors which are not very fundamental (as in influenza and myxomatosis) or by long-term factors such as those suggested by Mattingly

Prof D S **BERTRAM** referred to the fact that virus can pass more easily to the egg in ticks than in mosquitoes, having fewer membranes to cross in the process

Dr J S **PORTERFIELD** suggested that there are two time-scales in the evolution of viruses, one of which is short-term and is being witnessed now, as in the development of the Chikungunya virus

Dr M G R **VARMA**, who has worked on the Kyasanur Forest virus, pointed out that, experimentally, mosquito-borne viruses have been propagated in ticks, but not vice versa, which suggests that the tick-borne virus may be the more primitive Kyasanur virus is related to Russian spring-summer virus, but it is carried by hæmaphysalis and not by ixodes though these are abundant The Russian virus is transmitted by ixodes

Dr P B **STONES** observed that when mosquitoes first evolved there were no mammals, and if viruses then existed they must have been passed from mosquito to mosquito

Reviews of Books

Forensic Medicine

A KEITH MANT, M D, lecturer, department of forensic medicine, Guy's Hospital, London London Lloyd-Luke Medical Books 1959 Pp 262 42s

HERE is a well-written concise guide to the points which can be observed and the interpretations which may reasonably be made by general practitioners, police surgeons, and others called to see a body thought to be dead The book is intended also for those who may have to appraise injuries in the living or the dead, and for those asked to deal with an alleged sexual assault

When death is unexpected, it is very important that the initial examination of the body and its environment be conducted so that an opinion given at that time is well founded and not just a careless guess, otherwise, as Dr Mant points out, a family may suffer the early stages of an investigation of a supposed crime, later shown to be a natural death, or a murder may be unsuspected until after necropsy, by which time essential evidence may have been destroyed All that is described and well illustrated in this book is what may be seen by a careful observer, such as a general practitioner, no special forensic knowledge being required indeed, all specialised matters, such as necropsies, microscopy, and analyses, are excluded

What to do, and what not to do, when examining a supposedly dead body is followed by an account of up-to-date methods of estimating the time of death, the " virtual cooling time " method being explained in detail The characteristics of injuries, applicable to the living as well as the dead body, are dealt with at length, the examination of road accident victims being a useful feature Guns and gunshot injuries are carefully explained, and much attention is given to various causes of anoxæmia incidentally, perhaps the only illustration in the book to which exception might be taken is found at the beginning of the chapter on mechanical asphyxia Infant deaths, abortion, and poisoning conclude the first section of the book.

The second part deals with the medicolegal aspects of sexual offences, and any doctor who proposes to examine the alleged victim or assailant in a supposed sexual assault would be well advised first to study this section in detail, for incomplete physical examinations and incautious opinions based more upon preconceived notions than on fact seriously endanger the liberty or reputation of one of the parties involved Dr Mant leaves the reader in no doubt as to the responsibilities of the examining doctor in such cases, but he also offers a comprehensive scheme for a proper examination

As is apt to happen in a first edition, there are a few trivial points which will doubtless be amended in subsequent editions (e g, in the legend to fig 82, reference should be made to fig 77), but they in no way diminish the considerable value of this realistic work which can be wholeheartedly recommended to all involved in medicolegal affairs At the very least, Dr Mant shows the doctor how to avoid the unhappy thought, " What on earth am I supposed to see ? "

Antibiotic and Sulphonamide Treatment

A Short Guide for Practitioners A R ANSCOMBE, M S, F R C S, D B BROWN, M B, M M S A, M R C O G, D M DAVIES, M R C P Editor M E FLOREY, M.D London Oxford University Press 1959 Pp 150 10s 6d

THIS little handbook is designed as a brief practical guide to the treatment of infections It outlines the principal features of the antibiotics and sulphonamides and gives clear instructions for their use and adequate warning about their toxic effects and dangers It is fully up to date and includes notes on several recently introduced antibiotics

There can be little doubt that the book well fulfils its limited purpose, and those who want for quick reference a short text dealing only with the practical aspects of these agents will find it an excellent choice

THE LANCET

The Sign of Babinski

Since Babinski[1] [2] described the extensor plantar response in man, it has been generally accepted as indicating a disturbance of function in the pyramidal tract. Walshe[3] concluded that it was an integral part of the flexion reflex in man and was strictly homologous with the nociceptive flexion reflex in animals, described by Sherrington.[4] It has long been known that a transient extensor plantar response may follow an epileptic fit and may appear in biochemical disturbances affecting the nervous system, such as hypoglycæmia, so it is clear that the presence of the sign does not necessarily indicate an anatomical lesion in the pyramidal system. There has been some discussion and indeed criticism[5] [6] of the significance of the extensor plantar response as an indication of disturbed pyramidal function, and Brain and Wilkinson[7] have lately investigated the response in the human infant, using as stimuli pinprick and cold and, on the sole, key-drag.

They studied 35 children, ranging in age from one day to twenty-seven months. In children up to the age of eight days the responses obtained were almost always extensor and could often be elicited by pinprick or cold as high as the third thoracic segment, but the response was nearly always limited to the side stimulated. The greatest activity of the extensor response was seen in children between five and twenty weeks old, being obtained as a bilateral response to all of the three forms of stimulus applied to the sole, and it could also be obtained bilaterally as a result of stimulating either thigh. Usually a bilateral response could also be obtained from the abdomen and upper chest, but it was definitely or doubtfully flexor almost as often as it was extensor from these levels.

After the age of twenty-one weeks the receptive field shrank progressively from above downwards: only 1 child over the age of twenty-three weeks gave any plantar response to a stimulus above the third thoracic segment, and after the age of nine months there was usually no response to stimulation of the thigh. The response to stimulation of the sole also altered in character, the extensor response became less definite or was replaced by a doubtful or a frank flexor, but, even during the second year of life, the response to a scratch on the sole was not always flexor—sometimes it was a weak flexor, sometimes a weak extensor, and sometimes even a definite extensor. In general cold ceased to be an effective stimulus after the age of twenty-four weeks.

Brain and Wilkinson think it probable that the conversion of the infantile extensor response to flexor and the progressive shrinkage of the receptive zone between the ninth and twenty-fourth months of life can be correlated with the progressive myelination of the pyramidal tracts during this period.

Brain and Wilkinson also studied the plantar response in 31 children suffering from neurological disease dating from birth or very early in life, including cases of cerebral diplegia, and in 5 adult patients with virtually complete traumatic lesions of the spinal cord in the lower cervical region. In the children cold was rarely effective as a stimulus. A response to pinprick was evoked more easily the nearer the site of stimulus approached the sole, a response was obtained from the third thoracic level in only 4, from the abdomen in 13, from the thigh in 20, and from the sole in all 31. They conclude that the plantar responses of those children with congenital diplegia differ from those of normal infants in whom the pyramidal tracts have not become myelinated. In particular the usual absence of a response to cold and the extent of the receptive field of the reflex correspond more closely to patients with spinal-cord lesions acquired later in life.

Landau and Clare[8] examined the plantar response in 14 normal subjects and 12 patients with consistently extensor responses, using motion pictures and electromyographic recordings. In the normal flexor response the usual pattern included strong contraction of the short hallux flexors, with an associated response in the dorsiflexors of the foot, the extensor hallucis longus was always electrically silent. In the extensor response there was a tonic contraction of the short hallux flexors, contraction of the dorsiflexors of the foot and toes, and a strong contraction of extensor hallucis longus. The essential phenomenon of the extensor reflex is therefore thought to be the recruitment of extensor hallucis longus into contraction alongside the other toe and foot dorsiflexors, with mechanical overpowering of the toe flexors. In studying the changes in the response in several patients who had had acute spinal-cord lesions, Landau and Clare found electromyographic evidence of denervation in extensor hallucis longus and the dorsiflexors of the toes and ankles, and in 1 of these patients an extensor response became flexor in spite of evidence at operation of a virtually complete transection of the spinal cord. They thought that the denervation of the anterior tibial muscles in these patients was due to a lesion of the external popliteal nerve from pressure. In 1943 Lewin[9] also drew attention to the danger of pressure lesions of the external popliteal nerve in patients with spinal-cord injuries, although he did not study the effect on the plantar response.

These observations of the effect on the plantar response of a peripheral nerve lesion in a patient with severe spinal-cord damage are important and may well explain some of the recorded cases in which the plantar response was flexor in the presence of known damage to the pyramidal tracts. This is not, however, the only cause of flexor responses in spinal-cord lesions. Gordon Holmes[10] in 1915, studying acute injuries of the spinal cord, recorded a flexion-adduction movement of the toes as the earliest reflex response after a severe cord lesion, this reflex might disappear after a few days and later an extensor response might be found. This observation, confirmed by Riddoch,[11] is now well recognised and

usually indicates a poor prognosis for recovery of spinal-cord function BRAIN and WILKINSON observe that in 1898 SHERRINGTON had recorded a similar reflex in the monkey after transection of the cord below the level of the brachial enlargement, and that it has also been recorded in the baboon It seems that when all other spinal-cord functions are abolished there is a rather feeble flexor reflex of the toes in response to a stimulus to the sole, which GORDON HOLMES described as a " unisegmental reflex response in muscles supplied by the first sacral segment "

The Germ-free Animal

PASTEUR was usually right, but his reasoned guess that mammalian life without bacteria is impossible was proved wrong even in his lifetime The early attempts to raise germ-free animals were not very successful, but they failed not for lack of understanding of the problem but for minor technical reasons such as improper diets Today rats, mice, guineapigs, rabbits, and chicks are all raised free from parasites of all sorts, within and without, as a routine procedure which has proved valuable in many kinds of research Though this is not a cheap hobby for idle moments, the results seem to justify the trouble and expense A monograph from the New York Academy of Science [1] gives a good idea of the techniques and the results to be expected and will encourage others to try the method

On the same diets there is not much difference in the development of germ-free and conventional mammals Analysis of the weights of individual organs shows that heart and brain are of the same size, but the germ-free animal has far less lymphoid tissue If it is " infected " with a normal fæcal flora, the weight of lymphoid tissue soon reaches that of the conventional animal If, on the other hand, the conventional animal is fed small regular doses of penicillin from birth, the weight of its lymphoid tissue is not much more than that of the germ-free stock The development of the lymphoid tissue depends on the stimulus of the intestinal flora In chicks—as the farmer knows—small doses of penicillin quicken growth, and it has been debated whether this quickening is due to an inhibitory action of the flora of the bowel on growth or to some stimulant action of the antibiotic The germ-free chick grows at least as fast as the conventional bird fed with penicillin Of the various species of bacteria in the chicken's bowel which have been fed singly to the germ-free chicks, only *Clostridium welchii* (type A) slows the growth-rate to " normal " Germ-free mice grow well on a diet lacking some aminoacids essential to the conventional mouse If they are then given their normal intestinal flora they cease to grow there is not enough of something for both host and parasite Was the difference in size of adolescent boys in social classes I and V (which is no longer seen) attributable to some similar deficiency? So striking have been the facts elicited from these germ-free stocks that some biochemists are prepared to say that the science of dietetics must begin again from scratch

The serum of germ-free mice contains an abnormally large amount of albumin (and for this there is no parallel) but only small amounts of gamma-globulin It contains complement and properdin but no bacterial agglutinins unless the sterilised food contains dead bacteria When exposed to an antigenic stimulus, the germ-free animal responds more slowly than the normal The response to infections is curious and hard to understand In the normal animal fed by mouth, *Shigella flexneri* is not easy to establish, but in the germ-free animal 9 or 10 organisms introduced by the same route will multiply to 10^9 within eighteen hours Whereas these will produce no pathological changes, *Bacillus subtilis* causes a rapidly fatal disease, and the same is true of many other bacteria usually looked on as barely pathogenic Clearly the germ-free animal offers an opportunity to investigate the nature of infections in cavities of the body which ordinarily carry a large mixed flora We should be able to discover whether *Treponema vincentii* is the " cause " of an ulcerated mouth, or merely a normal inhabitant which takes advantage of existing disease to multiply exceedingly Many species of bacteria have been blamed for dental decay here is the possibility of examining their powers in isolation or in combination Experiments with germ-free guineapigs have shown that, while *Entamœba histolytica* can survive and multiply in the bowel wall, ulceration does not begin until the normal bacterial flora of the bowel is introduced On the other hand, the germ-free guineapig is susceptible to infection with species of worm whose natural hosts are the mouse or rat and which cannot be established in the normal guineapig

Though the scope for inquiry is limitless, such research is by no means all easy going For example, serum hepatitis can be established in one breed of germ-free chicks but not in another The evidence of the part played by viruses in the production of spontaneous tumours breaks new ground but is hard to interpret So far, moreover, few of the findings of this technique have had a practical application The premature infant delivered by cæsarean section and kept in a sterile atmosphere might reach viable size a few days earlier Almost the same benefit might be derived by feeding it small daily doses of penicillin, but he would be a bold pædiatrician who recommended this regimen Experience has taught that minor infections do quite a lot to protect us against the major ones If he was speaking of human life, PASTEUR was after all nearer right than wrong

The Role of the Stomach in Digestion

THE stomach makes two contributions to digestion it changes physically and chemically the food put into it, and it delivers its contents in a highly regulated manner to the duodenum The processes of digestion within the stomach and the control of the secretions which contribute to them have been so intensively studied that the dependence of eupepsia on the proper control of gastric emptying tends to be overshadowed Most medical students are made aware of BEAUMONT's *Experiments and Observations on the Gastric Juice and the Physiology of*

---

[1] *Ann N Y Acad Sci* 1959, 78, 1

Digestion (1833) and Pavlov's *Work of the Digestive Glands* (1916), but in fact digestion within the stomach is probably not essential for normal life It is usually accepted that the majority of patients with treated addisonian anæmia secrete neither acid[1] nor pepsin,[2] yet they are reported to be at least as healthy as patients of a comparable age[3] and not to be unduly susceptible to diarrhœa or dyspepsia[4] Although this view about the absence of pepsin in the gastric secretion of patients with addisonian anæmia is acceptable in a general way, some refined studies of gastric proteolytic enzymes by Taylor[5] have displayed new features which are too common to be called exceptional In an extension of earlier work[6] it has been clearly shown that gastric juice from normal persons gives two peak rates of digestion, one at pH 1 6–2 4 and one at pH 3 3–4 0 The activity at low pH is due to the classical pepsin,[7] but the cause of the second peak of activity at pH 3 3–4 0 is more controversial Taylor[8] measured the extent of digestion by the formol titration of carboxyl groups liberated from peptide bonds, and many of the digestion periods were long—three to six hours—by the standards of most other workers The measurement of carboxyl groups, which are produced in all stages of proteolysis, would be expected to give a different idea of digestion from that obtained by determining the rather special phenolic hydroxyl groups, as, for example, in the popular method of Anson and Mirsky[9] Under Taylor's conditions, with digestion periods usually of the order of three hours, as much as half the proteolysis by human gastric juice can be ascribed to a hitherto almost ignored enzyme acting at pH 3 3–4 0 Only 13 out of 23 patients with addisonian anæmia had even small amounts of proteolytic enzyme acting at pH 2 0, but 20 out of 23 had measurable activity between pH 2 6 and pH 5 0[5] From further study it seems that in gastric juice from man there are two main pepsins—that is, proteolytic enzymes acting below pH 5 0 Moreover, one of these predominates in the pyloric mucosa and the other in the mucosa of the fundus and body of the stomach[10] The results of an examination of gastric secretion from patients with peptic ulcer[11] or addisonian anæmia[5] suggest to Taylor that in some circumstances the gastric mucosa may secrete abnormal pepsins

The main change of view resulting from Taylor's work is that proteolysis in the gastric contents is not dependent upon such high acidities as was previously thought As a consequence it now seems possible that gastric lipase[12] and salivary amylase, which have maximal activity at very low acidities, and gastric proteases, could all act more or less simultaneously in the same medium

Having considered what types of digestion could take place in the gastric contents it remains to discover to what extent food is digested before it is passed into the duodenum In view of the usual presence of acid and pepsin in the gastric contents it would be expected that the gastric digestion of protein would make a significant contribution to absorption In the studies of Maltby,[13] who gave 100 g of fried minced lean meat and 300 ml of water as a test-meal, the aspirated gastric contents contained as little as 25% unaltered protein when the pH was between 1 and 2 Even when the gastric contents were as weakly acid as pH 5 about a third of the protein was found to be partly digested, which gives in-vivo support to the views of Taylor on the other hand, in Maltby's investigations patients with addisonian anæmia accomplished very little or no digestion of meat Although an exact comparison is impossible because of differences in chemical methods, it is interesting to compare the degree of digestion of meat under Maltby's conditions, which were particularly favourable, with that reported by Beazell[14] with normal meals which were recovered from the stomachs of 2 subjects who could vomit at will About 40% of the starch was digested in thirty minutes but practically none of the protein was completely digested Beazell also points out that much of the meal had left the stomach before digestion of protein had taken place

The idea that the stomach retains its contents until digestion is completed and only then transfers them to the duodenum should have begun to die with the appearance of Beaumont's monograph in 1833 and was convincingly refuted by McLure et al,[15] who showed that normal food began to leave the stomach within three to ten minutes of beginning a meal Nevertheless the concept of retention till digestion is completed is given in a current textbook Not only is gastric digestion of protein usually slow but much of the protein of a meal may have left the stomach before significant digestion could be achieved

Since the stomach has an incomplete action in digesting protein and begins to empty its contents into the duodenum very shortly after a meal is taken, it is reasonable to ask whether or not it makes any important contribution to digestive function Gastric emptying is not at all haphazard the rate of gastric emptying becomes slower as the concentration of nutritive material in the original meal is increased This regulation appears to be achieved via duodenal receptors which detect the products of hydrolysis of starch or protein, possibly by virtue of their osmotic pressure[16] There is the well-known slowing of gastric emptying in response to fat, which increases with the amount of fat in the meal[17] Gastric emptying is also adjusted in response to the initial volume of meals—for instance, the pattern of emptying with large meals is such as to give a sudden charge to the small intestine when the meal is eaten, followed by a slowly diminishing trickle of material which presumably matches the absorption [18]

Nutritional disorders *after total and partial* gastrectomy are common,[19] and their study has made apparent the part which the stomach plays in digestive processes In particular the effect on the total digestive processes of bypassing the duodenum has become clearer The masterly study of LUNDH,[20] using new techniques with radio-tagged fat and protein and an inert marker, has shown that after Bilroth-II operations there is a notable failure of mixing of trypsin with the intestinal content, the absorption of protein in his patients being more abnormal than the absorption of fat After partial gastrectomy LUNDH found that the absorption of protein was correlated with the concentration of trypsin in the intestinal contents, whereas in normal persons these values were independent This finding was taken to indicate defective peptic digestion, thus putting the tryptic phase under strain The current interest in the digestion and absorption of protein in such patients is a fitting response to the emphasis laid by BRAIN and STAMMERS [19] on the need for studying nutrients other than fat in patients with metabolic difficulties after gastrectomy

There is a big functional reserve to the various components of the digestive tract, and, other things being *normal, gastric digestion is dispensable*, but the gastric reservoir function is important for the proper time relationships between presenting material to the intestine and evoking the secretions of the pancreas Moreover, various subjective disturbances are common after *gastrectomy, apparently as a result of too rapid filling* of the intestine [21]

Annotations

MIRAGE OF HEALTH

WE are all specialists now, and it is notorious that a surgeon on biochemistry and a biochemist on surgery are equally likely to talk rubbish Such trespasses in other demesnes are not however always disastrous and can be most illuminating Dr René Dubos is one of the most distinguished of living bacteriologists and his essay, *Mirage of Health*,[1] ranges almost every field of medicine and far beyond The basis of his argument is that the formula

Host + specific parasite = specific disease

is seldom *if ever true Somewhere on the left side of the* equation are other factors, some of which we know so well that we tend to forget them and others which in our ignorance we have barely recognised Because perhaps Pasteur's *Memoire sur la fermentation* was contemporary with talk about "the struggle for existence", our profession has tended to treat all bacteria as enemies the only good microbe is a dead microbe If the slogan "Kill that germ" was applied conscientiously we would not only lack cheese and beer but most of us would die either of a deficiency of vitamins or by infection by organisms with which we now live in happy symbiosis There are, in fact, few bacteria which cannot survive in the human body without harm to either party bacterial disease is an upset of this mutual tolerance by the missing factors in the equation Even in such infections as gonorrhœa where these factors seem of small account a perfect prophylactic and treatment has not extinguished the disease For this we need an understanding of social habits which we have not got

History suggests that the most venomous epidemics are those imported into a society where the "causative" organism has been hitherto unknown Measles reduced the population of Fiji by one-quarter in one year (It is a curious fact that the import of diseases from the temperate zone into the virgin populations of the tropics has done far more damage than the reverse traffic Have our institutes of tropical medicine been looking in the wrong direction?) The lethal consequences of these introductions have been shortlived, and quite quickly adaptations in the host (and perhaps the parasite) make the disease no more deadly than it was in its original home At this moment the phenomenon is exemplified by myxomatosis in the rabbit The infectious diseases which plague us day in day out seldom come in epidemics but are the result of minor changes in the internal and external environments—fatigue, diabetes, perhaps worry—which supply the missing factors in the equation The deaths in concentration camps were due to our common diseases occurring more frequently and with greater virulence Our ecological balance is indeed precarious and (which is more important) always changing So long as the changes come slowly we can usually adapt ourselves to them individually and as a race Disaster is the consequence of great changes made too abruptly the sedentary man running for a train or the prize cattle breathing London smog One of the great difficulties of planning for health (or for war or even holidays) is that experience is of limited value We can do no more than guess the dangers ahead and our surmises are not always correct

Every civilisation has cherished a dream of perfect health and happiness, usually in the dim past or far far away Today we tend to look forward "Health is purchasable", and we see all round us new projects, new committees, and new buildings We owe much to the laboratory but perhaps not so much as we think The changes in environmental hygiene which freed us from typhoid and typhus—clean food, clean water, clean air—were devised and implemented by men who had never heard of bacteria Antibiotics have reduced mortality but may have added to morbidity By design the experimentalist limits the conditions of his inquiry to obtain a clear and certain answer The manifold factors which decide the larger issues of health and disease in ourselves, our homes, our community, and our nation are too complex as yet for comparable analysis Are our criteria of health beyond *criticism?* The legend of the "bonny baby" was exploded years ago and survives only at rural baby shows Those who talk comfortably of "the conquest of disease" should remember that at 45 our expectation of life is not much better than that of our grandsires every year we find it necessary to spend more and more on health (and in the U S A, Dr Dubos says, this amounts to 10% of personal income) and at least one in ten of us will spend some days, weeks, or months in a mental hospital

[1] Mirage of Health Utopias, Progress and Biological Change By RENÉ DUBOS London Allen & Unwin 1960 Pp 221 21*s*

On and around these matters Dr Dubos has written an exceptional book—plain, lucid, elegant, and lively. It draws its facts and illustrations not only from the corpus of medicine but from authors from Lao-tzu to Proust. It is logical and persuasive rather than dogmatic. It is in fact a confession of faith and humility by a great scientist. We commonly hear the complaint that the young doctor of today knows more and more about less and less. Reading Dr Dubos' book will make him a more useful member of our profession than an exact memory of the seventeen causes of enlargement of the spleen—and in this respect we are all young doctors.

PERTHES' DISEASE

Perthes' disease is now one of the commonest disorders of the hip in childhood. It affects children mainly between the ages of 3 and 8, and the symptoms are often trifling. There is occasional pain in the leg, a limp which may be difficult to detect, and some limitation of abduction and internal rotation. The radiographs may remain normal for some months after the onset of symptoms, but, when changes do appear, the head and neck of the femur undergo a slow process of disorganisation and reformation over a period of two, three, or more years.

O'Garra[1] distinguishes two types of radiological changes in the femoral head, depending on whether the whole of the head is affected, or only the anterior half or two-thirds, and suggests that the prognosis is more favourable with incomplete involvement. Of much greater importance is the age of onset and the sex of the patient. Using the final shape of the head as an index of resolution—and there is little else one can rely on in the child—there can be no doubt that girls do less well than boys. On similar criteria the younger the age of onset the better the prognosis. Until these two factors have been considered in O'Garra's figures, it is hard to tell whether partial head necrosis carries a better prognosis than complete necrosis, although the assumption seems reasonable.

No general agreement has been reached upon the pathogenesis of Perthes' disease. The radiological changes suggest an initial necrosis of bone, followed by reconstruction. Histological studies[2] of biopsy material from 23 hips confirm that necrosis affects the marrow, cartilage, and bone of the femoral head. Ponsetti[3] suggests that these changes are secondary to disruption of the epiphyseal cartilage plate, and are due to a disturbance of the blood-supply as the retinacular vessels cross the disrupted epiphyseal plate. That the lesion is one of avascular necrosis was first proposed by Legg[4] and is still the most commonly accepted view. Cavanaugh et al[5] suggested that osteochondritis of the femoral head is associated with a high incidence of colloid goitre in the families of affected patients, but Beiler and Love[6] were unable to find evidence of hypothyroidism in a group of patients with Perthes' disease. Similar radiological changes, however, may be present in the cretin and the mongol, and in the reticuloses and certain other general affections of the skeleton. In these conditions progressive destruction and replacement of the femoral head is absent.

Most patients with Perthes' disease are treated by some method which attempts to relieve weightbearing in the leg. In some centres rest in bed with traction is considered essential until the head begins to reform. Other surgeons suggest that a weight-relieving calliper is adequate, and Evans and Lloyd Roberts[7] believe that recumbency has no advantage over an ambulant method of treatment. Many would agree with Legg[8] that relief from weightbearing in no way affects the end-result. Before committing these children to a period of institutional treatment which may well last a year or more, two things must be established: firstly, that the prognosis of the untreated disease is sufficiently grave to justify this line of treatment, and secondly that prolonged treatment in recumbency improves the prognosis. Of the long-term effects of Perthes' disease little is known. Ratliff[9] has shown that, although radiological changes may persist in the hip into early adult life, function is rarely affected at this age. If, as seems likely, osteoarthritis is an uncommon sequel there can be little justification for long-term orthopædic treatment in childhood.

PROGNOSIS IN GENITOURINARY TUBERCULOSIS

THE place of combined chemotherapy in the treatment of urogenital tuberculosis is now so secure that it is hard to recollect the former ravages of the disease and to appreciate what has been accomplished. Barely twelve years have passed since the introduction of streptomycin (followed shortly afterwards by *p*-aminosalicylic acid and later by isoniazid), and a sufficient interval has only just elapsed to allow a full appraisal of its effect on what is often a chronic disease. In this respect the report of Gale and Kerr[10] from the Toronto Hospital for Tuberculosis is of outstanding importance, not only for its large number of treated cases but for the almost similar number of earlier cases which serve as a control. Historically Toronto has a special interest in the disease since it was here in 1929 that Harris[11] did his classical work on the association between renal and orthopædic tuberculosis. Some of his original patients are now included in a group of 82 cases followed for upwards of thirty-five years, and they represent an era when neither nephrectomy nor chemotherapy was in use. These cases give a remarkable picture of what used to be the natural history of tuberculosis, with a mortality-rate of 40% within five years and an eventual survival of 32% (described as "good chronics") in which something approaching symbiosis was fortuitously achieved between host and invader.

It might be assumed that with the subsequent vogue for nephrectomy in unilateral disease these morbidity statistics would improve, but in a further series of 347 consecutive cases treated where indicated by nephrectomy there was little apparent change. 43% died within five years, although 48% were still surviving over a period extending up to fifteen years. By contrast, however, the addition of chemotherapy—and in particular triple-drug therapy—is shown to be outstandingly effective. In a third series of 389 cases treated by a combination of nephrectomy (where indicated) and chemotherapy, followed for a period of up to ten years, the mortality-rate fell to 4%. Of the last 214 consecutive patients in this series receiving six or more months of chemotherapy none died from renal tuberculosis Whereas this phenomenal improvement is undoubtedly largely due to sustained triple-drug therapy, Gale and Kerr also acknowledge the ancillary benefit of certain conservative and reconstructive surgical procedures thereby made possible They rightly claim, however, that progress in the management of genitourinary tuberculosis during the past ten years ranks paramount among all the remarkable advances in urology within this period

TEMPERATURE REGULATION DURING FEVER

THOUGH fever is a very common accompaniment of disease or tissue damage, elevation of body temperature does not in itself clearly benefit the patient, except perhaps in a few special situations For this reason fever is sometimes regarded as a manifestation of failure of the normal controlling system, but this is far from the truth For many years there has been evidence suggesting that the body temperature is controlled at a higher level in disease

The concept of fever as a change in the setting of a central thermostatic mechanism was first formulated by Von Liebermeister,[1] and subsequent work by Stern[2] substantiated this hypothesis Stern observed the development of sweating or of shivering in patients with and without fevers, when they were warmed or cooled by gradually changing the temperature of a bath in which they sat He found that the change in rectal temperature when patients began to sweat or to shiver was the same in the pyrexial and apyrexial groups Subsequent experimental work in man has in general confirmed these findings Park and Palmes[3] found that the injection of bacterial pyrogens into normal subjects produced the same elevation of temperature in warm or cold environments All these findings suggest active regulation of body temperature during fever, though the evidence is not entirely conclusive

Further convincing evidence of active temperature control has been described by MacPherson[4] In a long series of experiments he obtained very complete records of the responses of three normal subjects to standard exercise during environmental heat stress During these experiments one subject developed a febrile illness characterised by cough and malaise, his temperature was raised by 0 5–1 5°F for six days During this time the subject was able and willing to continue with the experiment, thereby providing very interesting information

Before the onset of fever this subject responded to exercise with an increase of rectal temperature which was almost identical with that of his companions During the fever this pattern was exactly reproduced, at a higher level The absolute temperature increment due to exercise remained the same During exercise at moderate environmental temperatures the normal subjects showed a fall of skin temperature, with recovery during the subsequent rest period This pattern was also reproduced by the febrile subject, at a higher absolute temperature level During exercise this subject's sweat-rate did not differ significantly from that of his companions

These experiments confirm and extend the previous findings, suggesting that the febrile patient responds to various thermal stimuli in much the same way as the normal subject, but at a higher level of temperature It is difficult to avoid the conclusion that his temperature is regulated in the same way If the regulating mechanism is normally active, the temperature rise in fever must be actively produced Why this happens is unknown

B P C 1959

THE new edition[1] of the *British Pharmaceutical Codex* is dated 1959—a vintage year for official publications on prescribing costs—and against this background the *B.P C* assumes great importance The conscientious and selective use of the *Codex* by medical students and doctors would encourage the critical attitude and keener appreciation of the place of pharmacy in relation to therapeutics that can lead to prescribing which is both sound and economical

It is strange that the *British Pharmacopœia* (published under the ægis of the General Medical Council) continues to be a book of reference used almost exclusively by pharmacists, while the *Codex* (published by the Pharmaceutical Society of Great Britain) has become one of the most important books available to doctors The subject matter of the two is, of course, much the same, but there are striking differences in presentation Thus, the *Codex* includes paragraphs on the actions and uses of drugs these are not intended to convert it into a textbook of pharmacology, but they are invaluable in presenting concise information about the effects of drugs and the relative merits of their various preparations Thus, the *Codex* is a book of capital importance as an ancillary to standard works on therapeutics

Although drugs, or particular preparations of drugs, which have been deleted from the *Pharmacopœia* are likely to disappear also from the *Codex*, it is the traditional policy of the *Codex* Revision Committee to retain many of these preparations, if they are widely used, and look at them occasionally during a further period of five years There is clearly a place for this conservative attitude, for although the factual data of the *Pharmacopœia* and *Codex* inevitably have much in common, the books are in many ways complementary Allowance must also be made for doctors who are not prepared to modify their prescribing habits simply because, for various reasons, certain pharmaceutical preparations are no longer "official"

The additions to the new *Codex* include 70 new general monographs, and 20 of these refer to drugs already included in the *B P 1958* Among the monographs which deal with the more specialised materials (biological products, surgical ligatures, and sutures), poliomyelitis vaccine and rabies antiserum deserve mention The Formulary (part VI of the *Codex*)—perhaps the most valuable section for the prescriber—contains some 79 new items, but 44 of them represent "salvage" from those deleted from the *B P* There are long lists of deletions under monographs and under formulary Some 26 preparations suffer total eclipse, in that they no longer appear in either the *B P* 1958 or the *Codex* 1959 But few doctors will feel their withers wrung by the demise of infusion of quassia, solution of mercuric chloride, and the dilute solution of ammonium acetate The rise and fall of cream of penicillin (also among the 26 condemned to the twilight of obscurity) may, however, cause some to reflect on the transient glories of therapeutic fame

Public Health

EFFICACY OF AN ANTI-SMOKING CAMPAIGN

ANN CARTWRIGHT
B Sc Lond
F M MARTIN
B.A., Ph D Lond
LECTURERS, DEPARTMENT OF PUBLIC HEALTH AND SOCIAL MEDICINE, UNIVERSITY OF EDINBURGH

J G THOMSON
M.B Glasg, D.P.H
MEDICAL OFFICER FOR RESEARCH AND HEALTH EDUCATION, CITY OF EDINBURGH

THE scientific status of health education is not impressively high. Though more and more importance is attached to it as a function of the public-health services, there has been a notable shortage in this country both of theoretical analyses of the assumptions upon which health education is based and of evaluative studies of specific campaigns. Intention and effect have too often been confused, and the success of a programme has been measured by the enthusiasm with which it was planned and executed.

If educational measures are to be the principal means of trying to reduce current levels of tobacco consumption, assessment of their value is as important as assessment of the value of more conventional prophylactic procedures. Some local health authorities have already responded to the recommendation of the Ministry of Health and the Department of Health for Scotland that they should bring home to the public the health hazards associated with cigarette smoking, and many more may be planning to do so. The experience of the Edinburgh Health Department, which carried out a fairly extensive anti-smoking campaign and asked the University Department of Public Health and Social Medicine to evaluate its efforts, may therefore be of some interest.

The Campaign

The budget for the campaign totalled £4350—corresponding to about 2¼*d* per head of population—although certain additional money was available in the ordinary course of health education expenditure. The campaign was developed on the following lines.

Press.—Paid display-advertising material in which the Medical Officer of Health warned the public of the danger of cigarette smoking was accepted by all newspapers with a wide local circulation. Each of the three Edinburgh newspapers also gave the campaign powerful editorial support and provided much space in its news columns, gossip column, sports page, and photographic sections. Support from the national Press was considerable though less extensive.

Posters.—About 120 16-sheet posters were displayed on hoardings throughout the city, and about 3000 double-crown and crown posters were displayed in factories, offices, clubs, clinics, consulting-rooms, libraries, public baths, and shops. A poster was also shown in all the buses in Edinburgh.

Leaflets and letters.—30,000 copies of the British Medical Association's booklet *Smoking—the Facts* were distributed at meetings and to schoolchildren. A special Edinburgh campaign leaflet was designed by one of Britain's foremost display artists, and 150,000 copies were distributed through a variety of channels. A clear and forceful letter from the Medical Officer of Health was sent to every household in Edinburgh.

Meetings.—24 meetings were held at which over 2600 teachers heard the case against smoking presented by a doctor using visual aids in the form of a specially prepared flannelgraph and the B B C.'s film *Facts and Figures—Smoking and Lung Cancer*. Every class of secondary-school children was visited by a medical member of the Health Department. Meetings were arranged with almost all the parent-teacher groups in Edinburgh, at which the film *1 in 20,000* was shown. About 70 public meetings were held in different parts of the city in cooperation with various associations, clubs, &c.

Other media included a rally of voluntary workers, a concert for young people, a Sunday cinema meeting, and radio and television publicity.

The Evaluation

Two parallel samples of the adult population of the city were drawn, one sample to be interviewed before the opening of the campaign, in November, 1958, and the other to be interviewed six months later. The object was to discover any shift in the distribution of smoking habits and/or of associated beliefs.

The methods of sampling and interviewing have been described by Cartwright, Martin, and Thomson (1959a). 590 interviews were completed before the campaign and 596 after it; these correspond to response-rates of 85% after removal from the initial samples of those who had died or left their original address between the compilation of the electoral register and the survey period.

Smoking Habits

There was no indication that the campaign persuaded people to give up smoking. Similar proportions of people in the two surveys said that they smoked regularly—that is, at least one cigarette a day—and there was no significant change in the proportion who claimed to have given up smoking.*

The forms of tobacco consumption also remained unaltered; the ratio of pipe to cigarette smokers was similar on the two inquiries and there was no evidence that filter-tipped cigarettes or cigars had increased in popularity.

These negative findings are confirmed by the replies given to a direct question included in the second inquiry. Not one of our informants claimed to have given up smoking, even temporarily, as a result of the campaign, although, curiously enough, as many as 12% of all the people interviewed claimed to know someone who had stopped smoking because of the campaign. On the other hand, 9% of the smokers thought that their smoking habits had been influenced by the campaign; the majority of these claimed that they had been persuaded to smoke fewer cigarettes. Similarly, when the members of our samples were asked whether they were smoking more, less, or the same amount as six months previously, a comparison of pre-campaign and post-campaign replies suggested that a higher proportion of those interviewed in May, 1959, were under the impression that they had reduced their tobacco consumption. But when we compared the actual levels of tobacco consumption reported before and after the campaign we found no significant difference. It is very possible that the campaign succeeded in persuading a number of people to try to smoke less, and that in retrospect they may have felt their attempt to have been more successful than it was.

Beliefs about the Health Hazards of Smoking

Our November inquiry had shown that all but 2% of the adult population had already heard of the postulated connection between lung cancer and smoking, although many of them regarded the theory with varying degrees of scepticism. Hence there was virtually no scope for raising the level of public awareness of the hypothesis, and indeed after the campaign the proportion who maintained that they had not heard of it was still about the same

---

* Copies of statistical tables which give the findings in detail may be had from the authors.

On the other hand, there was a considerable opportunity to convince people that the hypothesis is correct Yet after the campaign the proportion prepared to accept it was found not to have risen significantly (P > 0 05) In spite then of the repeated warnings of the Medical Officer of Health almost as many people were still unwilling to believe that lung cancer is more likely in smokers than in non-smokers

In the first (pre-campaign) inquiry people were rather more ready to attribute such ill effects as coughs, breathlessness, bronchitis, and catarrh to smoking than they were to admit that it could cause cancer As these conditions were not mentioned in the campaign publicity, it was perhaps surprising to find a significant rise in the proportion who thought smokers more liable to breathlessness, bronchitis, coughs, catarrh, or heart-disease than non-smokers, although there was no change in the proportion who thought smokers more liable to indigestion, rheumatism, stomach ulcer, or tuberculosis

Similarly, although the campaign did not increase the proportion of smokers who supposed that smoking had affected their own health, it did produce a notable increase —from one in five to one in three—in the number who believed that their health might be adversely affected in the future This change was brought about by more smokers specifying breathlessness and cough as possible future effects, the proportion mentioning cancer as a personal risk did not rise significantly

This greater readiness to accept smoking as a possible cause of conditions which are more common and for the most part more trivial than lung cancer was wholly unexpected Two causal processes appear to be involved

The first of these could be a form of emotional blockage The widespread fear of cancer—long nurtured by a conspiracy of silence—generates a resistance that factual assertions do not easily overcome This resistance is strengthened by the feeling of guilt which may be aroused by incrimination of a habit which the individual knows that he ought to be able to control

The second process is one of deflection and dilution the charge against smoking is translated into terms which are more familiar and more acceptable Before the campaign there had been no great reluctance to concede that smoking might be harmful to health, and afterwards there was an even more widespread readiness to recognise its hazards But they are hazards more commonplace than lung cancer and on the whole far less frightening This latter tendency has affinities with the process of explaining the ætiology of major diseases in terms of simple everyday hazards, which we have called " reduction to the familiar " (Cartwright and Martin 1958, Cartwright, Martin and Thomson 1958)

The anti-smoking campaign, then, apparently heightened public awareness of some of the possible effects of smoking upon health, but did not increase acceptance of the idea that cigarette smoking may cause lung cancer

General Attitudes to Smoking

One of the more hopeful findings of the pre-campaign inquiry was that just over two-fifths of current smokers said that they would like to give up smoking if they could do so easily This proportion had not increased after the campaign, nor had there been any change in the pattern of reasons put forward for wishing to give up smoking Before and after, expense was most commonly cited, fear of cancer was mentioned by only 2–3% of smokers, and other health reasons were given by about one smoker in seven

Some change was evident, however, in attitudes towards smoking in young people Whereas before the campaign slightly under two-thirds of our informants felt it was " wrong " for young people to start smoking, by May this proportion had risen to just over seven-tenths Similarly, after the campaign, parents with children above the age of 15 were more inclined either to regret that their children smoked or to rejoice that they did not

Beliefs as to the advantages of smoking also seemed to have been modified slightly There was a little more scepticism about the view that smoking helps people to relax, 11% rejecting it compared with only 6% six months earlier Nevertheless it was still accepted by four-fifths of the post-campaign sample, while a similar proportion thought that a cigarette helps to relieve nervousness or embarrassment This latter fraction had not changed during the campaign

In general, then, there does appear to have been a very modest change in public attitudes There is certainly nothing to suggest that smoking was becoming socially unacceptable, but there was probably a slightly wider acceptance of the idea that one ought not to encourage young people to start it

Perception and Recall of the Campaign

To discover the extent of public awareness of the campaign, our post-campaign sample were first asked whether they had heard, seen, or read anything in the past few months about smoking and lung cancer Nearly three-quarters said that they had

Newspaper articles were recalled more often than any other form of publicity They were mentioned spontaneously by just over half our informants, compared with slightly more than a quarter who mentioned posters Other forms of publicity, such as leaflets and radio and television programmes, were recalled spontaneously by less than a tenth However, the proportions who claimed to have noticed the various publicity media rose appreciably when specific questions were asked. Newspaper publicity was recollected by a further 20% (so that altogether nearly three-quarters of our sample claimed to have noticed this) and two-thirds had seen posters The posters displayed on buses seem to have had substantially more impact than those on the hoardings Meetings and film shows had been attended by only 2% and 3% respectively Only 15% reported having seen a leaflet on smoking and lung cancer, though the Public Health Department had circulated 150,000 copies—one for every three persons in the city Similarly, rather less than a third said that their household had received a letter from the Medical Officer of Health, although such a letter was supposed to have been sent to every householder in Edinburgh

After asking questions about the specific aspects of the campaign, our interviewers said, " These things were, in fact, all part of a campaign about the connection between lung cancer and cigarette smoking Did you know there had been a campaign ?" Replies show that a fifth of the adults in our sample had been unaware of it

Men were rather more likely than women to know about the campaign More of them had read about it in the newspapers and seen the posters on the buses and on the hoardings There was no difference between the sexes in the proportion who had seen any films or leaflets, attended meetings, or received a letter from the Medical Officer of Health

The campaign also had rather more impact on younger than on older people The proportions who were aware of the campaign or who had seen the posters or who had seen a leaflet were significantly lower among people aged 55 or more In contrast, the proportion who had read anything in the newspapers did not fall off to any appreciable extent with increasing age.

The group of semi-skilled and unskilled workers and their wives was rather less aware of the campaign than those in skilled manual work, while the most widespread awareness was found among professional and blackcoated workers and their wives A similar trend was also shown for certain specific aspects of the campaign—newspaper publicity and letters from the Medical Officer of Health, but posters in buses were less often noticed by the middle-class members of our sample

These factors—sex, social class, and to a lesser extent age—are all associated with differences in smoking habits (Cartwright, Martin, and Thomson 1959a), the category of smokers, compared with that of non-smokers, contains higher ratios of men to women, of younger to older women, of unskilled to skilled manual workers, and of manual to blackcoated workers It is not surprising, therefore, to find that the impact of the campaign varies as between groups classified according to smoking habits The small numbers involved make cross-analyses difficult to interpret, but they seem to suggest that the variations may be explained largely in terms of the different sex, age, and social class characteristics of smokers and non-smokers respectively

Compared with people who were non-smokers or occasional smokers or people who had given up smoking, smokers were more inclined to say they had noticed something about the connection between lung cancer and smoking in the last few months On the other hand, they were less likely to have attended any meetings or to have noticed the letter which was sent to householders by the Medical Officer of Health. There was no significant difference between smokers, non-smokers, and others in the proportion who had read anything in the newspapers or noticed the posters on the hoardings, but among the non-smokers a smaller proportion had seen the posters in buses or were aware that there had been a campaign

Discussion

Although the anti-smoking campaign reached a large majority of the city's adult population through one medium or another, its coverage by no means equalled that achieved in the mass-radiography campaign a year before The latter, though concentrated into a much shorter period, had an impact upon almost the entire community (Cartwright, Martin, and Thomson 1959b) Newspaper and poster publicity in the mass-radiography campaign was seen and recalled by 95% and 91% of the population respectively, compared with 73% and 64% in the anti-smoking campaign

If it was ever expected to have an immediate and appreciable effect upon smoking habits, then the anti-smoking campaign must be deemed a failure, since our surveys showed no statistically significant shift in the distribution of these habits after the campaign Failure in this sense might have been predicted from the outset, for our pre-campaign inquiry had shown that, although 98 adults in every 100 had heard of the possible association between lung cancer and smoking, the number who had therefore given up smoking was very very small

Nor can the campaign be judged successful in having persuaded people that smoking does in fact increase the risk of lung cancer Unexpectedly, it increased the proportion of people who thought smoking harmful to health in other ways, but there was no parallel increase even in the proportion of smokers who would like to give up smoking if they could do so easily One cannot, of course, assume that a sustained campaign might not have a cumulative effect, the hardening of attitudes towards smoking among young people provides a hopeful indication, albeit on a modest scale Nor may it be taken for granted that a campaign whose focus was directly upon either the minor health hazards or the expense of smoking might not have more rapid and significant effects

It is arguable that educational campaigns of this nature are based upon unrealistic assumptions about perception and motivation But, although their chances of bringing about direct and immediate changes are extremely slender, they may in the long run help to change the climate of opinion in such a way that young people become less likely to start smoking Against this, the difficulty which habitual smokers experience in giving up the practice makes it improbable that large-scale changes can be accomplished until ways can be found of assisting the many people who would like to stop smoking but cannot do so by their own unaided efforts

Summary

A health education campaign in which the Edinburgh Public Health Department tried to bring home to the public the risks of lung cancer associated with cigarette smoking was evaluated by the Edinburgh University Department of Public Health and Social Medicine The evaluation was based upon interviews with random samples of the adult population of the city—590 before the campaign and 596 six months later

The campaign did not increase the proportion of non-smokers in the population, and the ratio of heavy to light smokers remained unchanged Nor was there any significant increase in the proportion who believed that smoking may cause cancer of the lung There was, however, a rise in the proportion who thought that smoking could be harmful to health in other ways—e g , in causing cough—though these had not been mentioned in the campaign

No change was evident in the nature and extent of smokers' ambitions to alter their own habits, but a greater proportion of those interviewed thought it undesirable that young people should start smoking

About three in four of our informants reported having been aware of the campaign, newspaper articles and posters were the only publicity media frequently mentioned Awareness of the campaign as a whole and of specific forms of publicity were found to vary with age, sex, and occupational class

Campaigns of this type are unlikely to produce changes in behaviour except possibly in an indirect and long-term fashion

This inquiry was supported by grants from the Chest and Heart Association (formerly the National Association for the Prevention of Tuberculosis) and from the British Empire Cancer Campaign We should also like to acknowledge the help and encouragement of Prof J H F Brotherston, Prof John Crofton, and Dr H E Seiler, and the valuable assistance of Miss Alice Stephen

Extension of Poliomyelitis Vaccination

The Minister of Health announced on Monday that the age limit for free poliomyelitis vaccination is being raised to cover all persons who at the time of their application for vaccination are under 40 The following small groups will also be offered vaccination

(*a*) Persons going to visit or reside in a country outside Europe, other than Canada or the United States of America.

(*b*) Practising dental surgeons, dental students, dental hygienists, student hygienists, dental surgeons' chairside assistants, and their families

(*c*) Practising nurses not working in hospitals (those working in hospital are already eligible) and their families

(*d*) Public-health staff who might come into contact with polio-

In a letter to local health authorities the Minister says these extensions are based on the advice of the Joint Committee on Poliomyelitis Vaccine At the same time the committee recommend that efforts should continue to be directed to the vaccination of as many as possible in the existing priority groups "Thus, although the acceptance rate among children born since 1943 is generally high, special efforts are still required in those areas where the rate is below the national average, and the need for raising the rate among expectant mothers continues in most areas Authorities have, with the co-operation of general practitioners, and by hard work and imaginative publicity measures, to a large degree surmounted the difficulties encountered in obtaining a satisfactory response from the group born between 1933 and 1942" Executive councils are also sending a letter to all family doctors about the extension of the programme

By the end of last year registrations for vaccination passed the 13 million mark Nearly all of those registered had had at least two doses of vaccine and over 7 3 million had received three In the 16–26 age-group, a total of about 2 7 million, or 46% of those eligible, had registered, and almost all had had at least two injections For children (1943–59 age-group) the acceptance rate rose to 75 4%, and 9 5 million had received two or more doses

The provisional number of cases of paralytic poliomyelitis last year fell below 1000 for the first time for 13 years the total was 914 The provisional number of both paralytic and non-paralytic cases was 1345, which was also the lowest since 1947. It compared with 2370 in 1958 The previous lowest total was 2177 in 1948. The highest number of cases notified in any one week during 1959 was 58 for the week ended Aug 22 The lowest figure was two cases during the week ended Dec 26 This is the lowest number for any week since the last week in 1946 when only one case was notified.

1959

Provisional figures for England and Wales in 1959 were published on Jan 23 by the Registrar General in his weekly return

The number of *live births* was 750,170—i e , 16 5 per 1000 population, which is the highest rate since 1949 *Infant mortality* was 22 0 per 1000 live births (22 6 in 1958, 23·1 in 1957, 23 7 in 1956, and 32 4 in 1949) The death-rate was 11 6 per 1000 population (11 7 in 1958 and 11 5 in 1957) The *excess of births over deaths* registered in 1959 was 222,596, the biggest since 1948, when it was 307,072 15,009 *stillbirths* were registered in the year, giving a rate of 20 7 per 1000 live and still births (21 6 in 1958 and 22 5 in 1957)

Health Statistics for Scotland

The Department of Health for Scotland has published the first[1] of a new series of annual reports giving detailed statistics about health and health services in Scotland. It deals with 1958 and gives more detailed figures over a wider range than have so far appeared in Scotland in a single volume

Until 1958, the annual reports of the Department of Health included statistical information about health services It was decided that the ordinary departmental report for 1958 (already published) should include only limited statistical material, and that a separate more detailed volume of health statistics should be published It includes population and other vital statistics and figures showing causes of death and illness in Scotland in 1958 Under some heads it covers a number of years before 1958 In the section on the hospital and specialist services, comprehensive figures are given showing the number of beds used for various types of illness in the regions, and the number of staff of different types employed in the hospitals There are also sections on the maternity services, infant and child health, and general medical, dental, and ophthalmic services Another section gives figures showing the cost of the health service under various heads

Conference

RADIATION PROTECTION AND MARROW TRANSPLANTATION

At a conference held at the Oak Ridge National Laboratory, Tennessee, on Jan 8–9, progress in protection against radiation was reported by various groups in the United States

D G Doherty (Oak Ridge) said that no recently synthesised compounds tested had been superior to aminoethyl isothiourea (AET), for which maximum protective effect in mice gave an LD_{50} of 1100–1200r D P Jacobus (Walter Reed) had obtained good results with mercapto propyl- and ethyl-amines, and with 5-hydroxytryptamine there was significant protection in mice and rats, but not in dogs, apart from slight delay in fall of white-blood counts. J Maisin (Armed Forces Institute) had used tritium-labelled AET to determine its distribution in the mouse after intraperitoneal injection Autoradiographs appeared to show widespread uptake in liver, spleen, brain, kidney, lung, and pancreas, and also in spontaneous tumours such as ovarian adenocarcinoma, hepatoma, angiosarcoma, and reticulosarcoma, but it was not clear whether the material was intracellular or not

Other workers in the Armed Forces Institute had shown marked protective synergism in mice, using AET and 5-hydroxytryptamine At 2500r there was only a 25% mortality V di Stafano (Rochester) had found AET to have acetylcholine-like effects on the gut, which were blocked by atropine both in vivo and in vitro

AET had been used clinically by J V Schlosser (New Orleans) in more patients There was no evidence of tumour protection, but so far there were too few controls to assess the degree of protection of the patient M. Kelly (National Cancer Institute) presented good evidence from controlled experiments in dogs that AET did not protect tumours, but did protect the animals against radiation J A Cohen (Netherlands) reported that the effect of AET on thymocyte protection in vitro correlated inversely with oxygen consumption and suggested that AET exerted its effect in vivo in this way

BONE-MARROW TRANSPLANTATION

N *Gengozian* (Oak Ridge) reported his findings of differences in the antigen recognition mechanisms in mice, using red cells of different species Sublethal irradiation lengthened the induction period following red-cell injection The more closely related the donor species, the greater the lengthening Young mice had longer induction periods than older mice and gave lower antibody titres For effective heterologous marrow transplants in irradiated mice, larger quantities of cells were needed for the rabbit than the rat, the hamster being intermediate W Dameshek (Boston) had shown inhibition of antibody formation to soluble antigens by rabbits treated with 6-mercaptopurine in doses of 3–6 mg per kg Such failure of response persisted for about six months, as judged by response to further challenges with the same antigen, but there was no failure of immunisation to other soluble antigens However, such prevention of acquired immunity could not be demonstrated with skin grafts, though with big doses of 6-mercaptopurine some delay of graft rejection was demonstrable E *Simmons* (University of Chicago) reported similar experimental results in rabbits using sublethal irradiation instead of 6-mercaptopurine

J W Goodman (Oak Ridge) had shown that when isologous heparinised whole blood was injected into irradiated mice, together with homologous marrow, there was an increased mortality, which did not occur if the blood was irradiated with 75r first In discussion many made the point that lymphocytes were possibly responsible *G Popp* (Oak Ridge) had shown graded survival of irradiated mice given different amounts of parental marrow, and on the basis of these results suggested that in human subjects too few marrow cells were being given On a weight-for-weight basis a 70 kg man should receive about 1 05 × 10^{11} cells—far more than is being given at present Dr Cohen showed that the interval between sublethal irradiation and time of injection of heterologous bone-marrow was extremely important in determining survival and incidence of secondary disease If bone-marrow transfusion was delayed until twenty-four hours after irradiation, survival was much increased. The possibility was raised that some cells responsible for "recognition" might persist in the host for some hours after irradiation.

J ANDERSON (Texas) reported rapid hæmatological recovery in monkeys given 2 5–3 5 $\times 10^{12}$ bone-marrow cells (isologous) three days after irradiation with 900r

Dr SIMMONS and others agreed that the chances of treating systemic tumours successfully by irradiation were poor at present. In rats and mice sterilisation of solid tumours and leukæmic tissue required about 4000r, whereas the present sublethal working limit, except possibly in animals treated with A.E.T and 5-hydroxytryptamine, was about 1500r, using A.E T or marrow transfusion alone. There was still a wide gap to be spanned.

Medicine and the Law

Drink and Diminished Responsibility

DESCRIBED by the prison doctor as a psychopathic personality, a 19-year-old soldier has been found not guilty of murder on the ground of diminished responsibility He was convicted of manslaughter under the Homicide Act 1957, and sentenced to life imprisonment.

The prisoner was charged with the murder in December, 1958, of a woman whose mutilated body was found in bed. The murder remained unsolved until last November when the police took his fingerprints in connection with another charge. After his arrest, the prisoner made a statement in which he described how he killed the woman, he also referred to attacks on two other women.

Dr Francis Brisby, principal medical officer at Brixton prison, said that, in his view, the prisoner had a psychopathic personality, which expressed itself in aggressiveness without sufficient cause and in criminal acts which induced no remorse or shame. When he was 15 his headmaster had described him as difficult and precocious Two years ago he had tried to hang himself For a year he had been drinking heavily He had claimed that he never committed any offence except when in drink. The encephalograph findings were abnormal.

Similar evidence was given by Dr Denis Leigh

Summing up, Mr Justice Donovan said that if the jury accepted the evidence that the prisoner was suffering from an abnormality of the mind which substantially impaired his responsibility for the killing, they should find him guilty of manslaughter instead of murder In his statement to the police, the prisoner had said "It is when I get drinking I do these things I am all right when I am sober" If a normal person got drunk or drank to excess and in that condition killed another, it would be no defence to say that he lost his self-control or that his self-control was diminished. The section in the Homicide Act dealing with diminished responsibility was not intended to be, nor was it, a charter for drunkards

His Lordship continued that two doctors had expressed the view that even if the prisoner did not drink he would still suffer from an abnormality of the mind which substantially impaired his responsibility "You are not bound by what the doctors have said. If you prefer to accept what the man himself has said, on the grounds that probably he knows best, you are entitled to do on that basis and say guilty of murder"

After the jury had brought in a verdict of manslaughter, his Lordship said that it would be unsafe to impose a sentence of a fixed term of years at the end of which the prisoner would be set free even if he were as dangerous as he was now The sentence must be one which would enable the authorities to detain him until they were satisfied that he could safely mingle with his fellow creatures once again.

It has for many years been a principle of English law that loss of self-control through drunkenness is not a defence to a criminal charge The summing-up in this case indicates that there has been no change in this principle as a result of the passing of the Homicide Act. The defence of diminished responsibility under that Act requires some abnormality of mind, and Mr Justice Donovan was surely right to tell the jury that mere drunkenness did not suffice

Medical Education

THE NEW AFRICAN SCHOOL

THE Nuffield Foundation has offered £250,000 to the University College of Rhodesia and Nyasaland towards the establishment of a medical school at Salisbury on the lines recommended by the Rhodesia Medical School Planning Committee This committee[1] has produced two reports, the first[2] of which proposed that a medical school should be part of the University College while the second[3] outlined a curriculum which has attracted much attention and was republished at some length in our columns[4]

The grant is offered on the understanding that the teaching hospital takes the form of a new multiracial hospital on the University College campus The planning committee's design for the medical course calls for more integration than is usual between the preclinical and the clinical parts of the course, and by putting the various departments in close proximity the University College has an opportunity to create a medical school which might become a model

When the new medical school is established, it will initially be an affiliated institution of the University of Birmingham The planning committee thought that the school should provide its successful students with a qualification which would be widely accepted, rather than with a diploma of only local value The University of Birmingham agreed to help over this, and the details of its relationship with the African college are now being worked out

While this relationship continues, students of the new medical school will be admitted to medical degrees of the University of Birmingham, and appointments to the staff of the medical school will be made only in agreement with the university For its part, the university will ensure that the shaping of the curriculum to meet local needs and opportunities does not affect the standard of the course or of the examinations required The relationship between the university and the university college will continue until the reputation of the new medical school is so securely established that local degrees which will be widely accepted can be awarded If thought desirable, the association of the two schools may indeed continue in some form after the university college has become a full university awarding its own degrees in faculties other than medicine

It is expected that very close personal relations will develop between the medical school at Salisbury and the medical school and the teaching hospital in Birmingham Staff will be exchanged and joint research undertaken It is being suggested, for example, that all members of the staff of the medical school at Salisbury should also be supernumerary members of the staff of the appropriate department in the Birmingham medical school When first appointed, they would spend a period teaching at Birmingham, and at intervals thereafter they would revisit Birmingham to engage, perhaps for a term, in teaching, research, and other departmental duties

In England Now

A Running Commentary by Peripatetic Correspondents

AIR travel is a chancy business at this season. At Rome airport we were told that the plane for Vienna might not be able to leave that night, because of fog at the other end. Until the weather, or the situation, became clearer, would we mind waiting? Dinner perhaps, at the company's expense? Inconvenience much regretted. Finally we boarded the Viscount about 7.30 P.M. There were only 2 of us, and I suggested to my companion that with the two charming, and unemployed, air hostesses we might try to make up a bridge four, but the unenterprising fellow preferred to sleep. We were making, not for Vienna, but for Stuttgart, where we picked up 16 stranded passengers from London. Vienna still being fog-bound, the plane's destination was to be Graz, and there, sure enough, we were decanted into a bus and conveyed to the station, where the airline representative dipped into his pocket and bought 18 first-class tickets to Vienna. At 1.15 A.M., now a rather morose band, we boarded the Balkan express, which fumbled over the 200 kilometres to the capital with no great zeal. Between snatches of sleep I listened to another of the 18 grumbling at the slowness of the train and the woes of all rail travel. But as, at 5.45 A.M., we crept out into the murky capital, I reflected that we should be heartily thankful for this old-world way which was there to serve us when the modern-wonder way had failed.

* * *

I was frightfully excited by the figures. A rough count showed a tremendous difference between the results for the patients who were getting my cherished new treatment and for the control group. Of course, I knew it clinically. But how splendid to prove it by statistics.

I have lately taken a course in statistics, so I knew what to do. I borrowed a calculating-machine for the weekend and roped in my wife—first to keep the children quiet, and then to work the machine for me. She grumbled occasionally and the children grumbled a lot. The cakes burned in the oven and the Sunday joint never got cooked at all. It was an unsatisfactory weekend from the point of view of human relationships and bodily comfort. But I didn't mind. I was much too busy covering sheet after sheet with my calculations.

At least, I didn't mind until Sunday night. Then I minded a lot. My results weren't statistically significant. I just couldn't believe it. The whole world seemed to crash about my ears. Then my wife made some coffee and reminded me soothingly that statistics never proved anything. I recovered sufficiently to write my paper. I became almost pompous about it. "Of course", I wrote with aplomb, "the fact that these results are not statistically significant only confirms our view that it is clinical judgment that counts, and in no way invalidates our findings."

Tomorrow I'll return that damned calculating-machine to its owner and never borrow it again. In future I'm going to trust to clinical judgment during the week and enjoy my weekends.

* * *

Copying case-histories for the files of the medical school is always somewhat of a problem, for the handwriting of house-physicians needs extensive study and a prolonged acquaintance with medical terms. Each new typist endows us with a series of usually infuriating approximations, but our latest indomitable novitiate, who refused to be beaten by any scribble, commands our respectful admiration. One of her typescripts runs:

> "Has been feeling 'dizzy' with his hypolemine drug recently. No pselpilatiars. No spircin. Very shallow complexion. Moderately dyspurcic with slight cyarosis. A/B Standing V space 5" fism midline. No mgms. CHF—JVP—O". H/S Triple rdtchin. Vesic breathing mcas. V/F nasal and equal parthride. Few asal eeeptitatioss. Check urine. Albunan + +. Furio NAD.
>
> 4.5.57. Mouth and throath sowing evidence of incease inflamation reddened day conked.
>
> 5.5.57. Has developed R. parohibis for pencillen and ghrepholugum.
>
> 6.5.57. Parabiba inversint. Pyrenial. Breathing with markde unspiratory thoidor. Indrowinping of chest. Acceuory unocles of perpuntior archive. Chonic truchihings of arms and head. Rehanded on submit."

Examples of her work are unhappily limited, for we felt it would be a pity to spoil her natural talent by an unduly prolonged acquaintance with medical literature.

* * *

I do not mind being called a stuffed shirt. Television-soaked teenagers can keep their gibes and their jargon. I belong to a different world of visual stimuli, old-fashioned, solid, three-dimensional, flickerless, and *mercifully silent*. Tucked away behind the stairs is the little room I call my study, with a bookcase full of faded medical textbooks and holiday brochures of places we could never afford to go to. A pleasant place for dreams and daydreams, away from the record-player, the radio, and the telly: an English oasis in the yackering desert of show business. If the stuffed shirt fits, I am proud to wear it; but I will not stand for any aspersions on my other stuffed and stuffy friends. A tiptop collection they are, too, all round my study wall. The pike from the edge of the reeds by the island: that was a bitterly cold day for spinning, and Jock Thompson knew how to trade on vanity when he charged me a deal too much for stuffing the thing. The otter pad from that morning when I fell in. The hare pad which was all that was left by the time we plodded up the hill on New Year's Day. The snarling fox mask over the door: he was the one that murdered a couple of dozen of our pullets one October night, and paid for them next day. Then there is the smiling fox by the fireplace. A friendly chap. I think I shall have all my fox masks mounted with their mouths shut in future. They look much more foxy and Corgi-like, much more ready to join in forty winks by the fire. Solid, silent, long-standing friends.

So I was pained to see an exhortation in the agony column of my favourite newspaper to get rid of the rubbish in our attics to some covetous box-number who wants to buy stuffed fish, animal heads, and similar trophies. Just like that. It seems so soulless. Can it be that some pools-winner is trying to purchase the priceless heritage of the still waters above our weir, some forecaster to cast his sordid golden lure towards my pike, some eight-draws expert to draw my coverts, to bid his twenty-four against my foxes' points, to back *his form against my hare's*? And then to have the unpardonable nerve to call them rubbish. And insinuate that I entertain my friends in the attic.

When the time comes for the last tidy-up of my study I shall command my executors to stuff the lot of us all in one box.

* * *

Village shopkeeper: "We're out of friars' balsam, but my daughter always rubs 'Vick' on Johnny's chest when he's poorly ... you did say it was for Carol, didn't you?"

Puzzled farmer's wife: "No, I said it was for our cow."

On reading the Registrar General's Statistical Review, Part II, Tables, Civil

In England, Nineteen Fifty Seven,
Many a good soul went to Heaven—
Many a woman, many a maid,
Many a man in many a trade,
And as for the income of them as passed over
Why some was in poverty, some was in clover.

There was some died o' drinkin' and others o' boxin'
And some hadn't taken their tet. antitoxin,
There was some died o' workin' and some had a trauma
(Although thanks to the Union I ain't feared of the former)
And a few had a sickness and some had a tumour
But a terrible lot o' them died of ill-humour.

In England, Nineteen Fifty Seven,
Many a good soul went to Heaven—
Many a Mister, many a Miss
Departed to eternal bliss,
But as to their religious sect,
It didn't make much odds, I expect.

Letters to the Editor

TREATMENT OF INGUINAL HERNIÆ

SIR,—As operations for hernia are about the commonest of all, we must commend the surgeons of St Thomas's Hospital and the investigators, Mr Shuttleworth and Mr Davies, for showing in your issue of Jan 16 that there is still no cause for complacency in the treatment of inguinal hernia. Few of those who embarked on the primary repairs of the 204 indirect and 94 direct hernias would have believed that 1 in 7 and 1 in 6 respectively would recur

One of the more solemn thoughts in connection with operations for hernia is that recurrences of even the third and fourth generation can be permanently repaired by a well-planned soundly executed operation, and all must agree with the authors that it is "difficult to escape the conclusion that the remarkable results obtained on recurrent herniæ are partly related to the extra care that is called forth by these herniæ" Doubtless the more experienced operators would also be called forth for the recurrent herniæ, and though we are all capable of making a botch of things from time to time, care, knowledge, and experience evidently help So much for the human factors

It seems that the method may also be a help, and Mr Shuttleworth and Mr Davies give general commendation to the nylon darn technique, for the 18 recurrent herniæ repaired by this method with no recurrence seem to be top of the bill, and results with nylon darns appear to be unbettered for those primary repairs more extensively used Has nylon any special properties to commend it in addition to it being easy to insert? I believe it has, for when it is used as a thick single strand it retains tensile strength even after long periods of implantation in the tissues Linen, silk, and cotton sutures and also braided nylon, floss nylon, and any preparation of nylon in the form of fine weave all have their tensile strength reduced to nil after six months in the tissues But the thick no 7 single strand of nylon retains at least two-thirds (and probably more) of its tensile strength after eleven years in situ, and though the tissues do have some effect upon all implanted nylon the thickness of the strand is sufficient to stand up to the weakening influence of the body's chemicals Thick strands darned into a mesh and lying in the fibrous tissue formed in and around a darn continue to act as part of the buttress and are especially protective during high strains The evidence in support of these facts has been submitted elsewhere for publication and calls for no elaboration here.

Those who may wish to try nylon as a darn in the inguinal canal should not be put off by talk of sinuses When nylon is used in closing incisions higher up in the abdomen after operations on the alimentary tract, sinuses undoubtedly occur at times, but the incidence of sinuses arising from nylon buried in the depths of the inguinal canal, even in patients with strangulation, is extremely low, and is far outweighed by the advantages Almost all sinuses after infection or hæmatoma will close if the infection is treated by antibiotic and the sinus by patience. Catgut does well in closing the external oblique, leaving the area pliant and the darn impalpable.

The Radcliffe Infirmary,
Oxford

G E MOLONEY

ESTIMATION OF BLOOD-ALCOHOL BY BREATH ANALYSIS

SIR,—I am a little perturbed by the rumour that the 'Breathalyzer' is to be used as a means of estimating blood-alcohol In fact, it measures the amount of alcohol in an aliquot of expired gas It is probable that in a healthy resting subject the vapour pressure of alcohol present in his alveolar gas will be in equilibrium with that in the arterial blood For many years now it has been realised that a sample of this gas may be obtained only from trained healthy subjects, such a sample cannot be obtained from untrained subjects whose lungs are at all emphysematous Moreover, the alcohol concentration in the expired gas of a given subject will depend critically on the rate of pulmonary ventilation, it should be easy for a partially intoxicated subject to hyperventilate for a minute or two before giving the required sample and thus halve the concentration of alcohol in his lungs The relation between the alcohol in expired gas and in the tissues, although explicable, is not at all simple I foresee many a happy hour spent in court by medical experts reconciling the results given by the breathalyzer with the facts of a case as presented by the prosecution or defence

F J PRIME

PULMONARY DIFFUSING CAPACITY

SIR,—The single-breath method of measuring the pulmonary diffusing capacity for carbon monoxide which has been modified and developed by Forster et al[1,2] has not fared well in your recent issues Firstly, Professor Melville Arnott (Jan 2) refers to Bates and Christie[3] who did not use the test and, secondly, Dr Jones and Mr Meade (Jan 9) have set about improving the test on an erroneous assumption The improvement depends on the recalculation of the breath-holding time to allow for the time taken to deliver the alveolar sample, and the assumption is that this is important because the alveolar sample is large and consists of several litres

The misunderstanding has undoubtedly arisen from the description of the method by Ogilvie, Forster, and others,[2] who state that all the expirate is collected after the first litre, which is rejected because it is contaminated with dead-space gas However, it is quite clear from their later discussion about different portions of expired alveolar gas, that only a small sample is required for gas analysis (approximately 300 ml) and that this is taken from the second litre From personal experience of making many measurements with Forster, I can state that in practice the collecting period is always kept as short as possible

It is doubtful if it is necessary to adopt the modified method for measuring the "effective" time of breath-holding except in patients suffering from severe impairment of the expiratory flow rate Since the problem then is to get a sample large enough for gas analysis, because of air trapping due to forced expiration, the error arising from large changes in alveolar volume during expiration, which is also mentioned by Jones and Meade, becomes unimportant

Department of Pharmacology
and Therapeutics,
Queen's College Dundee

R S MCNEILL

SIR,—Dr Jones and Mr Meade have put forward an ingenious and convincing explanation for the fall in pulmonary diffusing capacity which has been observed during breath-holding[1,2]

It seems that this fall is an artefact and can be abolished by timing the breath-holding periods from the start of inspiration to the midpoint in time (instead of the start) of sample collection, and then subtracting $^{3}/_{10}$ of the inspiratory time. It is questionable, however, whether the errors which they seek to overcome are either consistent or great enough to justify adopting their more complicated methods of timing and collection for routine clinical purposes

---

[1] Forster, R E., Fowler, W S , Bates, D V , Van Lingen, B *J clin Invest* 1954, 33 1135
[2] Ogilvie, C M , Forster, R. E., Blakemore, W S , Morton, J W *ibid* 1957, 36 1
[3] Bates, D V , Christie, R. V *Clin Sci* 1950, 9, 17

My colleagues and I[2] were able to collect adequate samples from each of our 28 untrained subjects in from 1 to 2 seconds In this group, Jones and Meade's timing corrections would have produced variations of about 5% in calculated diffusing capacity Providing that the subject is told to expire with all his might, he will add little to the sample after 2 or 3 seconds, although, in emphysematous patients especially, a noisy expiratory effort may continue for several seconds more When sample collection is continued beyond this initial period of 2 or 3 seconds, an error is more likely to arise if, as suggested by Jones and Meade, a fixed proportion of the total collection time is counted as time available for diffusion On the other hand, when the sample is collected within 2 or 3 seconds, these timing corrections seem scarcely worth while

I do not think therefore that the proposed modifications to the breath-holding test are necessary for ordinary clinical purposes, but I would like to congratulate Dr Jones and Mr Meade on their solution to a problem which has mystified workers in this field for a number of years

Stanley Road, Liverpool

COLIN OGILVIE

C-REACTIVE PROTEIN IN BURNS

SIR,—Your stimulating leading article of Jan 16 on the still very obscure and controversial subject of toxæmia of burns encourages me to recount some interesting observations which have been made on patients from our burns unit

It occurred to us that it would be worth studying the behaviour of C-reactive protein (C R P) in the blood of patients with burns, in the hope that serial quantitative estimations may provide a useful guide in the assessment and prognosis With this object in view a new technique for the qualitative and quantitative estimation of C R P has been developed in our laboratory It is based on immunodiffusion on cellulose acetate and permits the test to be performed on serum or on whole blood from a finger prick, thus enabling frequent serial estimations to be carried out even on children and severely burnt patients

We have carried out a series of investigations on patients with burns of widely different area, depth, and clinical severity In about 40 cases so far investigated we have found that the presence and the level of C R P in the blood appears to be closely correlated to the extent, depth, and severity of the burns Curves obtained from several estimations of C R P follow quite closely the progress of tissue breakdown and also the clinical state of the patient

A certain minimal amount of tissue damage has to be present before the C R.P can be detected With the same surface area involved, full skin loss produces a much higher level of C R P than a superficial burn In other words, the greater the tissue damage the higher the C R P level The presence of C R.P is detected within 24 hours from the time of the burn, sometimes even within 12–16 hours In moderately severe, uncomplicated cases progressing towards recovery the C R P level rises steadily and reaches a peak in about 5–7 days With uneventful recovery and satisfactory healing, the C R P level drops steadily until no more C R P can be detected In milder cases the increase of the C R P level may last only a few days

Complications involving further tissue necrosis, or acute inflammation with infection, may cause a secondary rise in the C R.P level, which may precede overt clinical manifestations, and thus indicate some unsuspected tissue damage In severe cases the C R P level rises steeply until a high titre is reached. Recovery is accompanied by a steady fall of the C R P level In fatal cases an abrupt drop was sometimes observed in the terminal stage This drop may coincide with the hypothermic phase In very severe burns, particularly in old patients, the rise in the C R P level may not be dramatic and will reach only a comparatively low level This might conceivably be associated with an overwhelming metabolic failure or, if death occurs in the first few days, the peak values may not have been reached.

The results so far obtained indicate that the estimation of C R P may be of considerable value in the assessment of the severity of burns, and of the efficacy of therapeutic measures (be they conservative or surgical), and may also be of some help in the prognosis The subject is now being investigated in detail, more material is being collected, and after a significant number of cases have been investigated it is intended to publish a full report

J KOHN

WITHHOLDING OF SICKNESS BENEFIT

SIR,—It was interesting to read that another medical man (Jan 23, p 228) had suffered the same treatment by the National Insurance set-up as myself Dr Edelston's prediction that to go on in an attempt to obtain redress is a waste of time and a foregone conclusion is only too true

After the first refusal I elected to go before a "tribunal" over my claim There were three members, and the chairman's opening gambit was that "if they leaned over backwards" there was nothing they could do about the matter One's immediate reaction was to say, Why waste my time and yours then? In the letter I received a few days later informing me that the tribunal had turned down my appeal was a notice that I could have my claim sent to the Commissioner in London. This I did, and after some 3–4 months back came a long screed putting the points of my case, but of course ending with a refusal to allow my claim, so, after all this, we were where we started

The whole thing is so unjust that I feel it needs thoroughly airing, and should be taken up in an attempt to get such infamous rules amended

Lenham, Kent

W A HERVEY

AN ILLNESS OF INFECTION IN CHICKENPOX

SIR,—Dr Partington (Jan 16) has I see resurrected the suggestion made by my late chief, Dr Edward Goodall, that an "illness of infection" occurs in measles, and he now puts forward his reasons for believing that a similar illness may occur in chickenpox as well

If an "illness of infection" actually occurs within a day or two of infection with measles, then it can only mean that the body defences have been effectively challenged by a score or two of virus particles to produce a vigorous defence reaction but one that is curiously lopsided For though the febrile component is well marked the antibody factories remain remarkably inactive Otherwise the virus, when in due course it had penetrated its target cells, replicated a millionfold, and burst into the bloodstream, would find itself, like the variola virus in a smallpox contact vaccinated a few days after exposure, confronted with a flood of antibodies But that does not happen here, the measles virus is in no way impeded and produces an attack of normal severity If the "illness of infection" were followed by an attenuated attack—or sometimes none at all—it might be credible, but as things are it would seem to be quite purposeless It is my general impression that the defence mechanisms of the body do not indulge in purposeless reactions

However, leaving theory aside, I remember that when Goodall first published his views I was then one of his very new junior assistants and I was naturally anxious to verify his observations Scope was abundant, because in those days with large open wards measles intrusion was common and exasperating Before convalescent serum became available, two or three cases might occur every fortnight until the supply of susceptibles ran out, meantime valuable beds were inactivated for weeks on end Diphtheria wards offered a particularly good field for observation as the disease was largely afebrile and the patients, although relatively long-stay, were kept under the strictest observation in view of possible complications But it ved impossible to correlate the occasional febrile episode t occurred with the subsequent fate of the patients The t majority developed measles without any sign, while those o exhibited what might be properly regarded as an "illness infection" did not develop it at all, or developed it at the t crop but one It was indeed impossible to confirm Goodall's ory, and this too was the experience of my colleagues

In the circumstances, the concept of an "illness of fection" is one which, in common with most experienced servers, I find myself unable to accept, and I would ggest that febrile episodes in the course of an incubation riod should be thoroughly investigated for some other thological basis Otherwise one may be doing a serious sservice to one's patient

Isleworth

G E BREEN

TRETAMINE IN THE TREATMENT OF INOPERABLE LUNG CANCER

SIR,—My communication of Jan 23 on this subject has sulted in a quite unexpected amount of publicity and orrespondence It is clear that some have interpreted the gures incorrectly and I should like to restate these in nother form lest many have been so misled 43 patients ere included Tretamine had no helpful action on 13 n 30 cases some subjective improvement was noted This as meant to imply that after the nausea had subsided they lt better, but in 20 there was no objective evidence of a avourable response

10 cases showed shrinkage of the tumours In the 4 escribed in detail and in the 3 who died of hæmorrhage, hese changes were observed radiologically The other 3 f these 10 cases (referred to in paragraph seven of the eport as "The remaining patients") had metastatic isease which was observed clinically to regress with relief f pain and a reduction in tumour bulk.

Of the whole series there are 7 survivors, including the referred to in detail.

I very much regret that this paper, prepared entirely by nyself and for which I accept full responsibility, has been o laid out as to be open to misinterpretation, and has hereby given undue hope or optimism to many people

Manchester

GORDON D JACK

CHEMOTHERAPY OF MALIGNANT DISEASE

SIR,—Your leading article of Jan 23 referred to the ailure of very high concentrations of chemotherapeutic agents to "cure" certain tumours It is possible, however, that the first chemotherapeutic "cures", or at least the first prolonged remissions have already been obtained I refer to the treatment of widely metastasised trophoblastic tumours by anti-metabolite substances Follow-up of such cases by Hertz[1 2] in the U S A extends up to four years, and similar cases have been followed without evidence of recurrence for eighteen months in this country

The success so far achieved with these tumours is partly due to the invaluable guide to therapy which is provided by sensitive, quantitative methods of assay of gonadotrophin excretion Gonadotrophin excretion appears to be a reliable guide to the amount of viable tumour tissue, and the well-recognised need for a similar guide to therapy in other forms of cancer is underlined. Whilst it does not follow that non-trophoblastic tumours will behave in the same way as those of trophoblastic tissue, it would be unwise to ignore the experience gained from treatment of the latter

For instance, widely metastasised choriocarcinoma has responded at least as well to moderately high plateau levels of anti-metabolites sustained for several days, as to much higher peak levels sustained for short periods Perhaps the most important observation from the treatment of these tumours relates to the futility of clinical and radiological evidence of remission as a guide to the need for further therapy Thus clinical and radiological remission often follows after one or two courses of treatment, whereas complete and sustained hormonal remissions are usually obtained only after seven to twelve courses of treatment extended over periods of four to six months

It seems likely that as a result of recent observations there will be increasing use of hormones, hypophysectomy, and the expanding range of chemotherapeutic substances in the treatment of cancer The widespread and haphazard use of these forms of treatment, however well-intentioned, can add little or nothing to our present knowledge The necessity for well-planned trials of these various methods used alone and in combination in a wide range of tumours is all too obvious, and it can be assumed that many clinical trials are already under way Need it be said that because of the sheer size of the problem there is equal need for some coordination of these trials, if effort and time are not to be dissipated

London, W 2.

K D BAGSHAWE

B C.G VACCINATION

SIR,—Your leading article last week puts into proper perspective a subject which has been surrounded by much turgid and irrational thinking in recent years

If, however, tuberculosis is to be controlled or eradicated, a curious gap in our knowledge and armamentarium must be filled I refer to the care of the children who are tuberculin-positive

So far great efforts have been directed towards protecting the tuberculin-negative groups by B C.G vaccination. With the fall in incidence of tuberculosis and consequent rise in the proportion of negative reactors, the law of diminishing returns comes into operation and the value of mass B C.G vaccination diminishes The group of tuberculin-positive reactors then assumes much more importance, because it is from this group that future cases will arise in the vulnerable periods of adolescence and early adult life.

If a positive tuberculin test in children means anything, it means infection by the tubercle bacillus, and not too long ago In all probability such infection will confer as much immunity as B C.G vaccination. It would therefore seem reasonable that these children should be treated as though they had primary tuberculosis, and given appropriate therapy This must result in a fall in the incidence of post-primary cases arising in later life from this group, and break one chain of infection. This would lead to an even more rapid decline in incidence and less need for mass B C.G vaccination.

The greatest danger that arises from the use of mass B C.G vaccination is that it renders ineffectual the tuberculin test as a means of identifying infected persons, and although this may be diminished by the establishment of a central registry, it would seem more important that tuberculin testing should continue to be used in identifying chains of infection, especially those arising from the largest pool of cases apart from immigrants—that is, the older age-groups These groups have been thrown into relief by the changing pattern in recent years, and can only be dealt with by more intensive case-finding and clinical methods

Effective drug therapy for tuberculosis has now been in use for at least ten years, and perhaps those with most experience could tell us whether the dangers and difficulties of drug therapy would outweigh the benefits to be obtained from its application to children who have become tuberculin-positive from natural infection.

HOTELS OR HOSPITALS?

SIR,—The stimulating articles in your issue of Jan 9 by Mr Stallworthy (p 103) and your peripatetic correspondent (p 109) are timely Many of our present troubles are due to a perpetuation of medical thoughts and actions common before the N H S began, but still regarded as sacrosanct

There are still too many small hospitals of less than 100 beds, dissipating medical and nursing manpower This is a small country most patients are really not so far from large towns and the larger hospitals, which could well be made larger with the money saved in closing small and inefficient units

Road and other accidents are surely going to increase Many are treated in small general hospitals ill equipped to deal with them A nationwide accident service is urgently needed, perhaps based on hospitals such as the Birmingham Accident Hospital Again, local medical, if not lay, sentiments must be overcome

Long waiting-lists are commonly held responsible for delay in admission Not enough thought is being given to why some lists are longer than others, not only in different specialties but in the same specialty in different areas Again, little effort is made to revise lists at regular intervals Who should do this? Certainly not lay record officers It would be revealing to know how many patients on particular lists have moved or been treated elsewhere, who have died, who will have refused treatment, and, most important, who may not need treatment after all This type of investigation again depends largely on medical cooperation and would apply to such conditions as "tonsils", chronic appendicitis, and D & C

As for the special problems of the fever hospital, it is true that many have empty beds, but when they are needed they are needed in a hurry Epidemics are unpredictable, and it is wishful thinking to say that they cannot happen here Surely the best analogy is the Fire Service, which equally ties up valuable manpower, material, and space

It is time that a more rational and less emotional approach to the value of good medical administration was adopted by all doctors Maybe this is a glimmer on the horizon

Chadwell Heath Hospital,

TREATMENT OF GALACTOSÆMIA

SIR,—In reply to the letter from Dr Schwarz and his colleagues (Dec 19) we wish to apologise for an error which was overlooked in our letter of Nov 14 Galactose-1-phosphate was actually expressed as micromoles not as microgrammes If the values quoted in our letter are transferred to microgrammes it will be seen that the two sets of normals are in agreement

Their suggestion that soya meal should not be used until it is "proved" safe surely would prevent its being used at all Strict proof that stachyose is not digested by the human infant can at present be obtained only by giving it to a galactosæmic infant and showing that this does not lead to an accumulation of galactose-1-phosphate in the erythrocytes Since stachyose and other compounds containing galactose occur in various other foods besides soya which are used in the treatment of galactosæmia a considerable amount of testing of these different compounds would have to be carried out, and in view of the limited number of galactosæmic babies available such testing might well take several years to complete In the meantime cases of galactosæmia are urgently needing treatment, and soya preparations may surely play a useful part as long as they are found not to cause an accumulation of galactose-1-phosphate in the erythrocytes

While the few cases we have so far treated with soya preparations cannot be taken to prove the safety of soya, such evidence as we have been able to get supports the belief that galactose is not liberated in sufficient amount to cause a measurable increase in the erythrocyte galactose-1-phosphate Clinical observations unsupported by chemical tests cannot on a short-term basis be accepted as proof of either danger or safety The failure to gain weight (apparently due to gastrointestinal disturbances) shown during a short period in the single case reported by Dr Schwarz and his colleagues need not have been due to galactose liberation We have seen a similar picture frequently when very young infants are placed abruptly on a synthetic diet If the new diet is introduced gradually over several days intolerance can be avoided

The addition of different foods to the diet of a galactosæmic infant may introduce a possible source of danger, since many baby foods contain appreciable amounts of lactose or other compounds of galactose It is necessary to discover what foods are galactose-free Jones and Leak[1] have given some indications of this in a recent paper, and we are now starting a study of the galactose content of weaning foods which we hope may give useful results

***At Dr Payne's suggestion we published a correction about the galactose-1-phosphate levels in our issue of Nov 28, but we failed to draw it to the notice of Dr Schwarz and his colleagues before publishing their letter We apologise to all concerned for our part in this misunderstanding —ED L

DENTAL DRILLS

SIR,—In your leading article of Jan 2 the possible risks to an operator using the new high-speed air-turbine instrument are discussed As you say, such risks may be caused by particles of tooth and old filling material propelled into the air by the blast of the turbine exhaust and by oil used in lubricating the turbine, which may be entrained in droplet form with the air-supply

Last year, at the request of Dr W G Senior, chief dental officer to the Ministry of Health, a preliminary investigation was carried out in this department on the environmental problems involved An 'Alston' drill was used In this instrument, the turbine is powered by an airstream which first passes across a vegetable-oil drip feed, while a secondary air-supply directs a jet of water on to the head of the bur At an operating air pressure of 40 lb per sq in the turbine speed was found to be approximately 260,000 r p m under no-load conditions

We did not measure the sound output, but a crystal pick-up, making mechanical contact with the turbine head, off load, showed a fundamental vibration of 4400 cycles per second, with some distortion, but not enough to suggest the presence of a high percentage of harmonics Thus, the major sound emission can be expected at this frequency

In order to study atmospheric contamination arising from drilling, four teeth, mounted in a cavity simulating the human mouth, were drilled continuously for 30 minutes, with an oil flow of 33 drops per minute, and a water flow of 2 6 ml per min An air sample, taken at a point one foot in front of the "mouth" and six inches above it, showed an average concentration of 1 3 mg oil per cubic metre of air Microscopic examination of a cascade impactor sample showed that the greater mass of both the oil and particulate matter was trapped in drops of water larger than would usually be considered "respirable" A second sample, taken during ten minutes of drilling, showed a calcium concentration from the tooth particles of 100 µg per cubic metre of air In actual practice the drill would not be used for as long as ten minutes, so that the concentrations obtained would be lower It was concluded from the experiment that there was little risk to the operator from the inhalation of oil or tooth particles under these circumstances

---

[1] Jones, N L, Leak, D *Arch Dis Childh* 1959, 34, 307

However, we would endorse the statement in your article that mineral oils used for lubricating purposes might provide a risk, mainly of lipoid pneumonia, and we wish to stress that the above remarks apply only to the use of a vegetable oil The question also arises of bacterial contamination by the blast of air from the turbine, but we have no observations as yet on this point

We have recently been informed that some dental surgeons have experienced irritation of the eyes and respiratory tract following the use of an air-turbine drill, and we would be interested to hear from others who have experienced any untoward effects

SKIN CHANGES IN HYPOCALCÆMIA

SIR,—Professor Dent and Dr Garretts (Jan 16) state that in their cases with hypocalcæmia " it is the lowered calcium level that is the main cause of the skin lesions " Observations of a similar patient with idiopathic steatorrhœa and erythrodermia make me believe that this statement is an oversimplification of the facts as far as idiopathic steatorrhœa is concerned

In July, 1954, a male of 22 was diagnosed by Dr Kenneth Perry as idiopathic steatorrhœa with exfoliative dermatitis His rash had begun some 8 years before and had become generalised. For 7 months there had been progressive weakness and pallor He was emaciated, pale, and almost bald. There was generalised erythrodermia and dusky brown pigmentation of the skin, with ectropion, and maceration and fissuring of the flexures The nails were rough and thickened. There were retinal hæmorrhages and exudates Chvostek's sign was positive The hæmoglobin was 15% (2 2 g per 100 ml) red cells 1,060,000, leucocytes 2400 per c.mm. plasma-protein 6 0 g per 100 ml. (plasma albumin 3 9, globulin 2 1) Serum-calcium 6 6, inorganic phosphorus 4 8 mg per 100 ml. acid-phosphatase 0 6 units and alkaline-phosphatase 10 units

The liver biopsy showed an excess of hæmosiderin pigment mainly in the Kupffer cells, and also to a slight extent in parenchymal cells and portal tracts Liver-function tests and blood-urea were normal. Barium meal and follow-through showed " steatorrhœa pattern " in small intestine. The sugar-tolerance curve was flat.

After treatment by blood-transfusion, folic acid, iron, vitamins, calcium lactate, calciferol, and a high-protein gluten-free diet, his general condition improved greatly and the anæmia and disturbance of serum-calcium were corrected, and have remained normal ever since. He has obtained work, maintaining television sets

Since June, 1959, his treatment has consisted only of a gluten-free diet. In September, 1959, his serum-calcium was 10 4, inorganic phosphorus 3 6 mg per 100 ml., and hæmoglobin 94% (13 8 g per 100 ml.)

Unfortunately the condition of his skin has not improved pari passu with the great improvement in his general condition. After an initial improvement in texture, diminution of pigmentation and exfoliation, the skin has remained for some 5 years red and finely peeling, and with intermittent ulceration of his pachydermatous lymphœdematous ankles

I think it is right to regard his erythrodermia as having been caused by a gross and broad nutritional deficiency—of protein, vitamins, and iron, as well as of calcium The failure of his skin to recover conspicuously may be due to irreversible damage caused by the great severity and duration of his disease, but I attribute the degree of improvement that has occurred to the correction of his protein, vitamin, iron, and calcium deficiency and to the dietary gluten restrictions, but not to the correction of his calcium deficiency alone

London, W 1

BRIAN RUSSELL

INTESTINAL ABSORPTION OF VITAMIN B_{12} AND THE B_{12} COENZYMES

SIR,—Dr Wasserman and his associates [1] recently commented on the paper by Reizenstein and Nyberg [2] and mentioned some experiments with the 5,6-dimethylbenziminazolyl cobamide coenzyme (B_{12Co}) isolated by Barker's group In this connection some of our experiments with non-labelled B_{12Co}* may be of interest

(1) Four patients with genuine pernicious anæmia were submitted to Schilling tests in which intrinsic factor (20 ml of gastric juice) was given with 2μg of radiovitamin B_{12} Before or after the mixing of the two, 15 μg of non-labelled B_{12} or B_{12Co} was added. The object was to study whether or not one of the two substances (B_{12} and B_{12Co}) was absorbed preferentially in the presence of the other (cf Bishop et al.[3]) Compared with non-labelled B_{12}, B_{12Co} had an equal or slightly weaker inhibitory effect on the absorption (urinary excretion) of radiovitamin B_{12} under the conditions used. In other words, B_{12} and B_{12Co} diluted the isotope in about the same way This fits in with the finding [1] in studies with liver homogenates that B_{12} and B_{12Co} compete in a 1 1 ratio

(2) The binding of B_{12} and B_{12Co} to gastric juice was studied in vitro If B_{12Co} was added first and radioactive B_{12} afterwards, the binding sites were occupied by B_{12Co} and the subsequently added radiovitamin B_{12} was able to displace B_{12Co} from some 30% of the binding sites Under the same conditions B_{12Co} displaces about 10% of previously bound radioactive B_{12} Thus the affinity of B_{12} for the binding sites is somewhat greater than that of B_{12Co} In addition, the same electrophoretic fractions of gastric juice were found to bind both substances In these experiments binding was assayed with both exhaustive dialysis and adsorption of free B_{12} to resting bacterial cells Since B_{12Co} is light-sensitive all experiments were performed under as dark conditions as possible

Thus, our preliminary studies indicate that B_{12} and B_{12Co} behave in roughly the same fashion In view of the indirect way we studied B_{12Co} (no radioactive B_{12Co} was available to us), we do not know whether it is absorbed better than B_{12} Supposing both compounds are taken up by the same acceptor mechanism in the intestinal wall, preferential absorption of one would be expected to inhibit the absorption of the other However, in our experiments B_{12Co} did not inhibit the absorption of radioactive B_{12} even as much as non-labelled B_{12} did. On the other hand, using radioactive B_{12Co} Dr Wasserman and his associates [1] found that the absorption of B_{12Co} is not so dependent on intrinsic factor as that of vitamin B_{12} This may perhaps be related to the weaker binding affinity of intrinsic factor preparations for B_{12Co}

NATURAL HISTORY OF CAVERNOUS HÆMANGIOMATA

SIR,—In view of the comments that my letter of Jan 2 provoked, may I be allowed to enlarge on certain aspects ?

In reply to Mr Murley (Jan 9), there were 1752 cases of cavernous angiomas or nævi and 814 cases were given superficial X-ray therapy No attempt was made to analyse this series in detail, for the paper quoted would have been as long as the original article by Dr Simpson (Dec 12)

My letter was not even a criterion of this excellently produced article, but merely to call attention to another viewpoint Do cavernous nævi across the Atlantic behave so differently from those in this country? I would consider American documentation quite our equal

I entirely agree with Dr Sneddon (Jan 16) that it is far easier to treat than to adopt an attitude of masterly inactivity, but there is surely some place for a mother's peace of mind to know that something is being done and that the disfigurement will go from baby in the minimum of time

My practice has been to treat all such lesions with thorium X varnish (2500 e s u per ml) once per month, and only where there was increase in size or failure to satisfy the parents, resort to superficial X-ray therapy

In reply to Dr Moynahan (Jan 23) none of the cases given superficial X-ray treatment was given more than 1200r units, and the majority reacted satisfactorily to smaller doses

I, too, examined many troops in the past war, although I could not claim to have seen 100,000 men, unless it was a march past I admit I too saw no evidence of cavernous nævi, but this is easily explained because I was not looking for signs of them, and the same applies to Dr Moynahan

I see their evidence now because I am looking for them, and can only offer Dr Moynahan an invitation to spend a pleasant weekend with me at the seaside and show him a few, commencing with one of my own sons

This brings me to another point Is it a good treatment to leave a child up to the age of 5 or 7 with a disfiguring blemish even if it is going to disappear spontaneously? Psychiatrists would have very strong views on this

I am convinced that superficial X-ray treatment reduces to a minimum the cases of spontaneous ulceration, and of course it is the subsequent scarring of these one sees later in life

In my own child, contrary to my judgment, I followed the advice of no treatment, spontaneous ulceration occurred, and there is certainly no maternal satisfaction, which I would remind Dr Moynahan was the criterion of cure Does he produce this by doing nothing ? I cannot believe it

May I remind readers that no dermatologist can have seen more children than Dr R T Brain, of Great Ormond Street, and it has always been his practice to give superficial X-ray therapy where necessary In a reported series of 614 cases [1] 147 lesions were untreated and they cleared up nearly as well, although not so quickly

I can think of many patients over the past 15 years who were dissatisfied with the rate of progress, but ready to wait patiently Very few would have been satisfied to sit back and see nothing done, and moreover the vast majority of family practitioners are relieved to know that these cases are being taken in hand

It can never be the genuine view of any that nothing active must be done, for several of the cavernous nævi in Dr Millington's and my series interfered with feeding, breathing, and vision Do our advocates of no treatment employ pipette or tube feeding, let the respiratory embarrassment remain, or allow the baby to grow up with monocular vision ?

I am grateful to Mr Denis Browne for the reproductions accompanying his letter of Jan 30 These illustrate very adequately the type of angioma that leaves persistent deformity

I am also grateful to Dr Brian Russell (Jan 30) for his excellent series, but here again I consider he supports our view If this baby had been his own child would he be prepared to just look at it for 6 years and do nothing? Would he be proud as father and dermatologist of his disfigured offspring? What about the mother's wishes, and I very much doubt if the last three blank spaces will show an absolutely normal lip—when he starts school his playmates will pull it and upset him

One of my surgical colleagues has just told me of a case that recently came under his care and was referred by him to the Royal Marsden Hospital The diagnosis was carcinoma of the thyroid and alleged to have followed X-ray therapy for a nævus, but he took the trouble to inquire exactly concerning this and found to his surprise that only thorium-X varnish had been used and no X-ray treatment given I imagine even the die-hards would hesitate to blame this form of radioactivity

Hove E COLIN-JONES

SIR,—I agree with Dr Ray Bettley (Jan 23) that the application of carbon-dioxide snow for 15 seconds will abolish a small superficial lesion, usually with a good cosmetic result, but unfortunately, especially on the face, an unpleasant and permanent dead-white scar occasionally results This is very uncommon after short applications, but I have seen it several times and am therefore reluctant to use such treatment It is much more debatable whether snow will " gradually improve all the rest " It is usually possible to decolorise the surface, but the deeper parts of thick lesions may persist, and accidents can happen

My teacher, Dr Sydney Thomson, once advised me that the first application of snow to a cavernous hæmangioma should never be for more than 5 seconds, with minimal pressure, in case of idiosyncrasy Although I now seldom use such treatment, I was recently prevailed upon by an anxious mother and a persuasive doctor to apply snow for 5 seconds to part of a lesion covering an infant's patella The resulting sloughing ulcer took six months to heal, after which the child required admission to hospital for manipulation before it could be induced to move its knee The end result was an unsightly scar in and around the treated area with spontaneous disappearance elsewhere

It is because of cases of this type, admittedly unusual, that I cannot agree that such treatment is " so simple, safe and effective that one wonders why anyone should wish to withhold it " This is, in effect, what Dr Colin-Jones and others have said of radiotherapy, yet most of us prefer to avoid it in so benign a condition, however rare unfortunate results may be

Hythe, Kent DENIS SHARVILL

SIR,—This very interesting discussion may be a vindication for " clinical impressions " as compared with statistics, for the value of which we have the opinion of Benjamin Disraeli I have read all the contributions with reasonable care, but nowhere can I find mention of the possibility of the " cavernous hæmangiomata " becoming malignant in after years This outcome must be rare, but it does happen, and is therefore a point in favour, perhaps, of operation I have seen one such case, in a girl aged three years, who had her " cavernous hæmangioma " removed at operation, only to succumb to a sarcoma, primary in the operation scar, about the age of fifteen

---

[1] Brain, R T , Calnan, C D *Brit J Derm* 1952, 64, 147

The obvious course seems to be, "keep the patient under observation" for many years if possible One advantage of operation is that sections can be studied, much can be learnt from careful study

St Margaret's Hospital,
Epping

FRANK MARSH

SIR,—Will you please allow me to thank all of your correspondents who have shown such an interest in my paper on this subject and to make a few comments?

My aim was to provide more factual information, in rather more detail than had been published before, for the benefit of those who have already seen the light and whose chief concern in the early stages is to allay parental anxiety The subsequent correspondence confirms my statement that the majority of dermatologists in this country agree with the views I expressed and it is reassuring to learn that both general and plastic surgeons are following the same policy

With regard to nomenclature I claim neither originality nor authority but merely tried to define the terms used

The point raised by Mr Denis Browne as to whether really early treatment of small lesions is justifiable or not can only be decided by investigations, such as I and others have been attempting in the past thirty years, and it is disappointing that Mr Browne can deduce so little evidence in favour of his very definite opinion in favour of treatment.

The only evidence I can offer is that out of 25 lesions of more than 3 cm. diameter 11 (44%) had disappeared without trace at 5 years and the others were all resolving satisfactorily, moreover in only 10 of these 25 cases had the lesion grown rapidly, i e., faster than the child. Like Dr Dowling, I have never seen a really large hæmangioma arise from a tiny spot. On the other hand, last year I saw an infant with over 100 small dermal lesions, of which none grew as large as 1 cm. in diameter and all showed signs of resolution by the 6th month.

Surely a few years' maternal embarrassment is of less importance than the patient's cosmetic appearance in adult life.

Exeter

J R. SIMPSON

KURU AND SPORADIC TREMOR SYNDROMES IN NEW GUINEA

SIR,—Wilson et al[1] reported 24 cases of various tremor syndromes found sporadically in a population of about 100,000 natives in the Western Highlands of New Guinea and they have described 3 of these cases as examples of a kuru-like syndrome They believe that "the implications of these newly discovered neurological disorders for the kuru problem are great" In fact, they go on to say, "If the genetic hypotheses are correct, Melanesian natives may possibly have an unstable locus in their chromosomes at which mutation to produce inborn defects of metabolism leading to cerebellar, basal-ganglionic, and generalised central-nervous-system diseases of the kuru type is likelier than among other races" Later on, after making what appears to be a contrary suggestion that "a single kuru mutation might be assumed to underlie both syndromes", they say "the ethno-environmental variables which determine altered clinical and epidemiological expression must be elucidated" I think it needs to be made clear that no supporting evidence for these various genetic ideas has been put forward

No genetic investigation has been described for these sporadic tremor syndromes And there is no justification for assuming that the genetic hypothesis which has been put forward and found to hold for kuru[2-4] should also be charged with accounting for these different rare tremor syndromes found in another part of the island Some of these disorders may indeed have a genetic basis but this awaits demonstration It is unlikely that a genetic study could be made quickly, for the mere accumulation of genetic data for such sporadic disorders would probably be a very slow business But even if some of these syndromes should be shown to have a genetic basis and this did depend, in fact, on a single locus, this would provide no support for the view that an "unstable locus" is involved Furthermore, one can entertain such a suggestion only by ignoring the distinctive and significant family patterns in respect of kuru which have been found throughout the region concerned.[2-4] A high mutation rate at the kuru locus would not help to explain the astonishingly high frequency of kuru in the Fore population of the Eastern Highlands—surely the most puzzling and significant feature of the whole kuru population problem.

The population genetics situation presented by kuru may be unique, but our understanding of this tragic situation will not be advanced by confusing this uniqueness with a high degree of improbability for a genetical cause for which there is no evidence In contrast with the suggestion made by Wilson et al that these new syndromes may be "clinical variants of kuru and related to it in pathogenesis", may I express the hope that further work will enable those workers to make a clear distinction between these sporadic syndromes and kuru—as indeed they are already distinguished in a number of important ways

Department of Genetics,
University of Adelaide.

J H BENNETT

MEDICAL NEEDS OF INDIA

SIR,—Your interesting and sympathetic leader last week refers to the scheme of postgraduate training "going back to a committee formed in 1941 under the chairmanship of the late Sir Bennett Hance"

The Commission of Inquiry into Future Health Needs of India was in fact presided over by the distinguished Indian statesman, Sir Joseph Bhore The Bhore Commission was composed of individuals drawn from many walks of life—political, financial, sociological, and medical—and obtained evidence from an impressive array of witnesses from India and oversea, including an advisory body from England under the late John Ryle, with Janet Vaughan and Weldon Dalrymple-Champneys, Professor Ognev from Moscow, and others from America and Australasia

The Bhore report is a classic in the assessment of medical needs of an underdeveloped country

London, S W 1

GEORGE R MCROBERT

NEW WORDS REQUIRED

SIR,—In response to Mr Caplan's request (Oct 31), I suggest he may wish to consider a variation on the root word *errare*, to wander

In current usage, aberrations are "slight deviations from the normal course" to navigators, while to astronomers an aberration is "a slight apparent shifting in position of a heavenly body", so the root word "aberrant" seems to be a natural choice for Mr Caplan's purpose

My suggestion is the neologism "aberract" to denote a variation from optimum conduct

Physical Restoration Division,

Parliament

Population (Statistics) Bill[1]

Dr **Edith Summerskill** regretted that in introducing this Bill to the Commons on Feb 1 Miss **Edith Pitt**, parliamentary secretary to the Ministry of Health, had not explained more frankly the reasons why powers were sought to obtain further information about stillbirth and fœtal abnormalities, the age of fathers, and the duration of pregnancy Dr Summerskill thought that the information asked for in the schedule made it clear that the Bill was related to the genetic effect of nuclear radiation The Minister had never been persuaded to admit that the increase in congenital abnormalities and in the incidence of leukæmia might be partially due to radioactivity Yet here they had a Bill the import of which every scientist would know precisely, and an opening speech which had not for one moment touched on the real reason for its introduction

Mr **Derek Walker-Smith** agreed that part of the object of the Bill was to find out more about the incidence of congenital abnormalities They were acting on the advice of the Medical Research Council Even if the number of mutational births was very small indeed, nevertheless there was something here which we had to study The Medical Research Council was anxious to study it, and the Government were anxious to give the Council the facilities and scope under this Bill which would enable it do so

QUESTION TIME

Preludin (Phenmetrazine)

Dr **Edith Summerskill** asked the Minister of Health whether he now proposed to prohibit the sale, without medical prescription, of 'Preludin'—Mr **Walker-Smith** replied The Home Secretary, as an interim and urgent measure, has asked the Poisons Board to advise him which of the substances referred to by the Interdepartmental Committee should be limited to supply on prescription, under the Pharmacy and Poisons Act, 1933 The Poisons Board has held a meeting to consider the matter and he expects its report very shortly Dr **Summerskill** May I remind the Minister that the whole question of the administration and consumption of this dangerous drug, preludin, was considered in this House a year ago after comments had been made in a coroner's court? Since then, there have been other fatalities Could he not at least prohibit the sale of this drug without medical prescription? Will he read the report on the drug industry by a subcommittee of the Senate in the United States? In view of the fact that American firms are making such headway in this country, should we not take warning from the revelations which were made to the Senate last week?—Mr **Walker-Smith** The question of this drug can be dealt with only under the procedure of the Pharmacy and Poisons Act, 1933 An interim report by the Interdepartmental Committee was received on Jan 21, the Poisons Board has already met, and the Home Secretary will be very shortly making his statement in regard to action

Working Party on Legislation on Medicines

Mr **Gresham Cooke** asked the Minister if he would give particulars about the Interdepartmental Working Party which he had set up on legislation concerning medicines—Mr **Walker-Smith** replied This Working Party has been set up by the Secretary of State for Scotland and myself, in consultation with the Home Secretary, with the following terms of reference

> "to review the legislative provisions which relate to the control of medicinal substances and to recommend what changes should be made to rationalise and simplify the law with a view to ultimate amendment and consolidation"

It consists of 12 officials from the Government departments mainly concerned, of whom 2 have medical, 3 legal, and 2 pharmaceutical qualifications, and it will receive evidence from the organisations that are expert in this field

Hostels for Mental Patients

Mr **N N Dodds** asked the Minister what progress was being made in providing hostels for people now confined in mental hospitals solely because there was no other provision for their welfare, in view of the desirability of enabling them to regain their liberty and self-respect as members of the community—Mr **Walker-Smith** replied Local authorities have made a start in providing hostels of various kinds for the mentally disordered It is likely that the main effect at first will be to avoid hospital admission for those not in need of it rather than to enable hospitals to discharge patients, local authorities and hospital authorities have, however, been asked to consult together in assessing future needs for the provision of hostels

Poliomyelitis and Infective Hepatitis

Mr **L A Pavitt** asked the Minister of Health what was his department's policy regarding the treatment of poliomyelitis and infective hepatitis in open wards Mr **Derek Walker-Smith** replied I have conveyed to hospital authorities the view that patients with any infectious disease should normally be nursed in isolation and recommended certain precautions to be observed when it is necessary to nurse such patients in open wards I have suggested that special hospital units should be provided where practicable for the treatment of poliomyelitis

University Places

Mr **Malcolm MacPherson** asked the Chancellor of the Exchequer, with reference to his announcement on Feb 20, 1958, of a building programme for the universities for 1960–63, related to an estimated rise of student numbers to 124,000 in the mid-1960s, with the possibility of a further increase of 10% in the second half of the decade, whether he would not consult with the University Grants Committee as to the desirability of relating the building programme to higher numbers than these—Mr **Heathcoat Amory** replied The University Grants Committee last year made a full examination of this question in the light of the latest estimates of future numbers of seventeen and eighteen-year-olds in the schools and of other relevant factors As a result they recommended strongly to me that they should be authorised to discuss with the universities an expansion of their capacity beyond the figure of 135,000 places which had already been agreed They proposed to explore the possibility of providing an additional 35,000 to 40,000 by the late 1960s or early 1970s and to etsimate the capital cost involved I have authorised this action and I understand that discussions with the universities have already begun

Approved School Inquiry

In a statement on the recent report on the disturbances at an approved school, Mr **R A Butler**, the Home Secretary, said that it included some general recommendations not requiring legislation With these he was broadly in agreement, especially on the need for securing an adequate number of trained housemasters, and for pressing forward with plans for modernising and improving accommodation He agreed also with the view that a limited provision of secure facilities was necessary to deal with the minority of difficult and troublesome boys with a disruptive influence on normal training

The proposals involving legislation presented greater difficulty, and needed consideration in relation both to the legislation about the treatment of young offenders, which was foreshadowed in the Gracious Speech, and to the wider questions affecting approved schools The Ingleby Committee had also under consideration some aspects of these questions He would therefore prefer to defer further comment on the proposals for amending legislation until he had considered them in relation to his suggestions in the whitepaper He was sure that the House would wish him to make comprehensive proposals for the treatment of young offenders, even if this involved some delay in introducing the Bill which was being prepared

Obituary

WU LIEN-TEH

M A , M D Cantab , LL D

PHYSICIAN to the Emperor and successive Presidents of China, director of the Manchurian plague prevention service, and director of the Chinese National Quarantine Service are unusual appointments for a Cambridge graduate to hold, but Dr Wu was an unusual man Fifty years ago, by his dramatic conquest of an outbreak of pneumonic plague in Northern Asia, he won an international reputation, he retained and enhanced it by his later work as a scientist, administrator, and writer

He was born in 1879 in Penang where his father was a goldsmith As one of a family of eleven children he had to make his own way in the world, but he won a Queen's scholarship, open to all the Straits Settlement, and he entered Emmanuel College, Cambridge, in 1894 At Cambridge, and indeed until he moved to China, he used the Cantonese-Malayan form of his name and was known as Gnoh Lean-Tuck He took a first-class in the natural sciences tripos and in 1902 qualified from St. Mary's Hospital With a research studentship from his own college he continued his bacteriological studies at the Liverpool School of Tropical Medicine, the Pasteur Institute in Paris, Halle University, and the Selangor Institute at Kuala Lumpur In 1904 he returned to Penang and spent three years in general practice

In 1907 he was invited to join the Chinese Government service at Tientsin and in 1908 he became vice-director of the Army Medical College. In 1910 he was sent by the Manchu Imperial Government to Harben to try to suppress a virulent epidemic of pneumonic plague that was killing over 100 people a day He was given a dangerous and desperate task, for he had to organise plague hospitals and a plague service out of nothing

In his autobiography, *Plague Fighter*, which appeared last year, he has described the desolate scene the ground was covered with snow as far as he could see, and dotted here and there were groups of destitute refugees coughing and spitting blood—candidates for certain death Wu had no protection, not even a mask, and his associates had no idea of the dangers of droplet infection They stood before the unfortunate victims, huddled into corners, and breathed in their breath Small wonder that nearly half the doctors and nurses died It was impossible to bury the dead, for the ground was frozen iron-hard Instead, they had to build high funeral piles and burn the corpses soaked in paraffin

By organising medical assistants, nurses, and orderlies, by separating contacts, by isolating the sick, and by fumigating the homes Wu succeeded in three months in controlling the outbreak He also succeeded, as he reported at the International Congress on Plague over which he presided at Mukden in 1911, in tracing the infection to the marmot hunters—poor men who hunted the giant marmot (or tarabagan) and caught the infection from the pelts hanging in their miserable huts The tarabagan and the allied species of suslik were recognised as reservoirs of plague in the steppes and deserts of Manchuria and Siberia

In 1912 the Manchurian Plague Service was set up and inevitably Wu became its first director The Government allocated large sums for plague hospitals and the service became in effect a pioneer public-health service Wu's classical treatise on *Pneumonic Plague* was published in 1926 In 1930, when the National Government established a quarantine service, Dr Wu became director and equipped quarantine stations along the Chinese coast and at all important ports He retired in 1937 to Ipoh, where he had begun his medical work, and there he continued in practice throughout his alert and active retirement He died on Jan 21

During his varied life Wu received varied honours He was a mandarin of the second rank and an honorary graduate of Johns Hopkins University He had been decorated by the Czar of Russia and the President of France He sat on many advisory committees of the League of Nations and he was a founder of the Chinese Medical Association Of this versatile man P M -B writes

"Whatever the politics or whatever the revolution in his country, Wu lived and worked through it all He was a world authority on the opium trade, and he was interested in cholera, anthrax, narcotics, quarantine, and venereal diseases He never stopped writing, he attended every available medical congress in every continent, and he was known to everyone He never forgot his English friends, and he would turn up in London, now and then, to take up the threads, reminisce on his undergraduate days, and tell of his heroes, amongst whom he numbered Patrick Manson and Andrew Balfour In his massive autobiography, which is full of stories of his adventures, he showed himself as the great family man, proud of his family, proud of his offspring, and always proud of his Western contacts and forgiving for the sins of his European friends "

SAMUEL RONALD SINCLAIR

M B , B Sc Belf , F R C S E , D O M S

Mr S R Sinclair, ophthalmic surgeon to the Royal Victoria Hospital, Belfast, died on Jan 18, while on holiday in London He was 47 years of age

He was the youngest son of the late Mr Samuel Sinclair, of Cadogan Park, Belfast, and was educated at the Royal Academical Institution and Campbell College, Belfast, where he played in the rugby XV and the cricket XI He graduated B SC at Queen's University in 1933 and took his medical degrees three years later He was a house-physician in St Thomas's Hospital, London, before the war, and in 1939 he joined the R.A M C and served in the Middle East as a specialist in ophthalmology with the rank of major On his return he took the F R C S E in 1947 and was appointed a consultant by the Northern Ireland Hospitals Authority He was on the staff of the Royal Victoria Hospital (where he was honorary secretary of the medical staff committee), of the Ophthalmic Hospital, Belfast, and of other hospitals in the Province At Queen's University he was a clinical lecturer in ophthalmology

T W D writes

"Sam Sinclair was a scratch golfer who captained the University team in 1936 and won the Irish mixed foursomes championship in the same year He was a member of the Royal Belfast and Royal County Down Clubs and of Strangford Lough Yacht Club His skill, efficiency, equanimity, friendliness, his quiet manner, and sterling character endeared him to all of his colleagues, the nursing staff, and his patients in whom he took a deep personal interest "

Mr Sinclair leaves a widow and three daughters

EDWARD WEISS

M D Jefferson

Dr Edward Weiss, professor of clinical medicine at Temple University School of Medicine, Philadelphia, has died at the age of 64 He was a founder and past president of the American Psychosomatic Society

H R R , who in 1953 as a Fulbright scholar worked with Dr Weiss in Philadelphia, writes

"It was an inspiration to discuss with him any problem in psychosomatic medicine, for he had a profound knowledge of clinical medicine and dynamic psychiatry and a razor-like intelligence He had a way of formulating his opinions, both verbally and in writing, so that they appeared on the surface disarmingly simple In his most recent book, *Don't Worry About Your Heart*, which was meant for the intelligent lay public, this adroitness is beautifully brought out

"Edward Weiss was highly cultivated, a superb host, and a most generous friend and colleague Among the social organisations to which he gave his time and skill were the Family Society of Philadelphia and the Marriage Council of Philadelphia He was an earnest Anglophile, and in one of my last conversations with him only last December he outlined his plan to return to England in the next year or so to explore and paint the Cotswolds "

Notes and News

WORLD HEALTH ORGANISATION

SPEAKING to the Executive Board on the malaria eradication campaign, Dr M G Candau, director-general of the World Health Organisation, said "we had no illusions that the campaign would be easy, but the problems are being solved and if eradication fails it will be not for technical reasons but because we have not got the money to carry it out."

According to information received by W H O from Governments, of the 1,238 million people that lived in originally malarious areas of the world, 258 million had been freed from this menace by the end of last year Another 641 million live in the 65 countries and territories where eradication programmes are in progress, and 95 million are in 33 countries and territories which have realistic plans for such programmes The board was told that the problem of mosquitoes becoming resistant to residual insecticides has proved not to be insurmountable and affects only 30 million people or less than 5% of the total number in areas where eradication programmes are in progress

Mr M Siegel informed the board that there was an estimated shortage of 1 3 million dollars to finance W H O's share of costs of malaria eradication for 1960 as at present planned, and that 6 4 million was needed to ensure continuation of the work in 1961, even at the slightly slower rate of progress that had been projected He deplored a situation in which over 95% of the 11 6 million dollars received before the end of 1959 had come from one member Government—that of the United States Among the other countries that had contributed, few were among the more economically developed, and some had the lowest per-capita incomes of the world During the discussion the situation was improved by the announcement of a new contribution by the U S S R of 1 million roubles in services and supplies, and another of £15,000 by Australia The Government of Norway intends to propose a contribution of 100,000 dollars to Parliament as soon as W H O can announce that a certain number of other member States will contribute sums of the same relative size A contribution of 1 million German marks from the Government of West Germany is also foreseen, and on Jan 26 the board learned that the Canadian Government is asking Parliament for a contribution of 100,000 dollars

The United States has made the first donation (300,000 dollars) to W H O's Special Account for Community Water Supplies which was set up last year to give technical assistance to Governments

W H O's intensified programme of medical research was commended by Prof Lowell T Coggeshall (University of Chicago) as "intelligent" and practical It will give high priority to services to research—e g, the standardisation of nomenclature, techniques, and equipment, the establishment of reference centres for the identification of microorganisms, tissues, parasites, &c , and the improvement of communications among research-workers and of their training Next in priority will come demographic studies of the prevalence of diseases, and international coordinated research projects that may have a bearing on major W H O programmes

The hope was expressed that such research will tie nations together, establishing official contacts between research units that formerly only individuals achieved This is already being done by bilateral agreements, Dr Candau told the board, citing the agreement between the U S S R and the U S A providing for, in part, exchanges of experience in the field of health and medical science[1] Dr Candau hoped that this move will lead to worldwide cooperation on a similar level, both Governments using W H O to bring other countries into the sphere of their cooperative efforts Prof V M. Zhdanov (U S S R) said that scientific institutions all over the world must further W H O's research programme He predicted that in time it will become one of the most important activities of the Organisation

---

[1] See *Lancet*, Jan 23, 1960, p 233

The Government of India has invited W H O to hold the Fourteenth World Health Assembly in New Delhi in 1961 Though the Assembly usually meets in May, this meeting will probably take place in February, when the Delhi climate will be more propitious

COST OF PHARMACEUTICAL SERVICES

In his review of the Appropriation Accounts for 1958–59 [1] the Comptroller and Auditor General notes that the continuous increase in the cost of the pharmaceutical services of the National Health Service persisted during 1958 Though the number of prescriptions dispensed fell from 228 million in 1957 to 224 million in 1958, their total cost rose from £68 million to £73 million and the average cost per prescripton from 5*s* 11½*d*. to 6*s* 6½*d* A growing proportion of these prescriptions were proprietary preparations (51% in 1958, as against 47% in 1957 and 37% in 1955) Proprietary preparations also accounted for a growing proportion of the cost of ingredients (72% in 1958, 70% in 1957, and 65% in 1955) Most of them, according to the classification of the Cohen Committee, are not therapeutically superior to standard preparations

As their estimated cost to the N.H.S was £30 million in 1958–59 (as against £20 million in 1955–56) the Comptroller, not unnaturally, was interested to have news of the voluntary price regulation scheme introduced in June, 1957, for a trial period of three years The Ministry of Health had estimated that the scheme would save the Exchequer up to £750,000 on an annual expenditure of £20 million. In fact, on an annual expenditure of £28 million the scheme had only saved £412,000 One of the chief reasons for this was that ten drugs which had been expected to show price reductions of 25%–40% had in fact qualified for the export price criterion and no reduction had been obtained. According to the published accounts of 43 pharmaceutical firms for 1951–53 their percentages of profits had been above those of general industry and had lately tended to increase whereas the rate for general industry fell The profit rates of the British subsidiaries of American concerns had consistently been much higher than those of general industry The Comptroller freely admitted that these figures showed only very general trends and that many of the firms had important interests unconnected with the N.H.S But he had noticed that a firm (whose profit in 1957 apparently exceeded 100%) in producing a proprietary drug on which the N H S spent a large sum paid a substantial royalty on any crude material not bought from its American parent. The Comptroller was interested to note that more than half the N H S expenditure on proprietary preparations was on the products of firms which achieved only 3 2% savings under the voluntary price regulation scheme. Because of the proportion of drugs excluded from price control and the industry's high rate of profits he doubts the efficacy of the scheme. The Ministry, however, believe that the scheme had imposed " some restraint on prices and led to some reductions "

TRAINING IN GENERAL PRACTICE

An experiment in training for general practice, financed partly by the Nuffield Provincial Hospitals Trust, is taking place in Winchester A graduate intending to enter general practice holds a supernumerary appointment, paid at registrar rates, in hospital for one year, during which he obtains experience in various special departments according to his needs, including a six-month appointment in obstetrics and gynæcology, if he has not already held such a post. For the second year he is attached to a general practitioner, under the general-practitioner training scheme, to gain experience of aspects of medical practice other than his own. He is also introduced to the local-authority medical services The object is to produce a general practitioner thoroughly versed in the many aspects of modern general practice, and to study methods of achieving this end.

The first appointment was made in Winchester last August and further appointments will shortly be made in Southampton and Portsmouth. Another hospital appointment will be available in Winchester in August, 1960, when the present holder moves into general practice under the scheme An advertisement appears in this issue

LADY EWING MEMORIAL

The work of the late Lady Ewing in the cause of the education of deaf children won worldwide renown, and the high reputation of the department of education of the deaf at Manchester University sprang largely from her remarkable skill as a teacher Her friends and former students now feel that this recognition should take a more permanent form and that some suitable memorial to her life and work should be established. They believe that many people, especially those whom she helped directly and indirectly, would be glad to contribute to the cost of its foundation It has accordingly been decided to establish a research scholarship to be known as the Irene Ewing Research Scholarship Contributions should be addressed to Mr F W Cockersole, 80, Wellington Road, Edgbaston, Birmingham, 15 Cheques should be made payable to the Lady Ewing Memorial Fund

---

University of London

Dr E B Chain, professor of biochemistry at the Istituto Superiore di Sanita, Rome, and scientific director of the International Research Centre and head of the biochemistry department, has been appointed to the university chair of biochemistry at the Imperial College of Science and Technology from Oct. 1, 1961 Professor Chain was awarded in 1945 a Nobel prize for medicine jointly with the late Sir Alexander Fleming and Sir Howard Florey for their work on penicillin

The Isaac Wolfson Foundation has given the college £350,000 to build and equip laboratories for biochemistry and chemical microbiology in Professor Chain's department and for the support of teaching and research The equipment of the Wolfson Laboratory will include fermentation units of comparatively large size and workshops for advanced mechanical and electronic equipment. It will provide accommodation for training and research in the borderland between biochemistry and chemical engineering, and for research on the biochemical production of chemicals

Mr Kenneth McLay has been appointed reader in otology at the Institute of Laryngology and Otology

University of Edinburgh

Dr E S Blackadder has been appointed part-time lecturer in the general-practice teaching unit and Dr R F Robertson member of the clinical teaching staff in the department of medicine.

University of Birmingham

The following appointments have been made

Sir Arthur Thomson, senior fellow in medical history, Dr R F Fletcher, lecturer in the department of medicine, Dr J D Blainey, part-time lecturer in the department of experimental pathology (metabolic diseases), Mr J A Williams, lecturer in the department of surgery

University of Exeter

On May 4 the honorary degree of LL.D will be conferred on Dr C. J Fuller

Royal College of Obstetricians and Gynæcologists

At the meeting of council on Jan. 30, with the president in the chair, the following candidates were elected to the membership

Armaity Aspandiar Anklesaria, Alison M Armstrong, M P Awon, Amarendra Banerjee, J D Begg, Kwesi Kobea Ogye Bentsi-Enchill, K. G Bland, Kathleen A S Brosnan, G R. Brown, Solomon Burgin, Biman Kumar Chakrabarti, Supriya Chakravorty, F R Clark, Harry Cohen, J B Comerford, F G Cox, Gerda J Crow, M M De La Harpe, R. A Don Sheila L B Duncan Solomon Ende, P H Foote, A C Fraser, K E Free, I K Furler, W T Gallagher, Susan George, Ronald Giles, C S Hanson, P D Hill, Uriah Jacobson, Snehalata Bhujanga Kamath, Pun Shui Kan, Swadesh Kataria, Brendan Keane, Bhabesh Chandra Lahiri, Ariffin Bin Ngah Marzuki, Tanendra Nath Mitra T Khoon-Fong Ng, D B Pantin, Heather M Panton, Mary C. Royal College of Physicians of London

At the comitia on Jan 28, with Sir Robert Platt, the president, in the chair, the following, having satisfied the censors' board, were elected to the membership

G M Ardran, M D Lpool, John Bamforth, M B Cantab , M A Barraclough, M B Lond , J R Billinghurst, B M Oxon , E J M Bowlby, M D Cantab , D E Christian, M B Lond , G W A Dick, M D Edin , P M S Gillam, M B Cantab , Maurice Gross, M B Lond , D D Guttman, B M Oxon , R M McCredie, M B Sydney, William MacKenzie, M D Lond , A B Myles, M B Cantab , K A K North, M B N Z , H L Nossel, M B Cape Town, E D O'Callaghan, M B Queensland, P T Pickens, B M Oxon , Mohamed Sadek Sabour, M B Ain Shams, N L Schwartz, M B W'srand, P J Scott, M B N Z , R S J Simpson, M B Queensland, J H Stewart, M B N Z , Weland Dinnis Stone, B M Oxon , Vetherednam Thuraisingham, M B Malaya, W E Watson, M B Lond

Licences to practise were conferred on the following candidates who had passed the final examination of the Conjoint Board

J H Ainsworth, E G Anderson, R B Andrews, R I A A Aubee, J K Bandoh, Sheila A Beningfield, C A C Bennett, R P Bishop, P G H J Bosley, Margaret Bown, Isobel J N Bradbury, J S Brewer, M G Brook, Diana C Brown, J P B Budgen, R G Bury, Janet R Carruthers, M E Carruthers, Francis Carter, Margaret E Cash, Anne J Cawthorne, M J Chamberlain, Glen Champion, M J S Coe, Bertha C A Coker, T J Colbridge, G P Coleman, Heather J Collins, D H Coombe, A S Cooper, Linda F Courtier, C S D Crane, T W Darling, Faram Dastur, H R Davies, J G Deller, E R Dixon, M W O Dunwoody, Kathleen J B Edwards, Ekpo Ita Efiong, Mary Ellis, M D Farrar, J T L C Fernando, A E Finnigan, D J Fishlock, P R Goddard, A B Griffiths, J B Gritton, J H Hackwood, Edna Hallam, D R Harvey, I B Hayter, Ann Henley, Pauline B Hird, K E F Hobbs, R C Hodge, G T Hollingworth, A S Horner, Peter Howard, E G Hoyen-Chung, K E E Hubble, M K G Hudson, W F G Hulley, M J Hunter, R -K R Innes, Peter Jackson, C W Jamieson, Rosemary Khin Zaw, R S Kirk, Elizabeth S Kitchin, C C Korvin, A P Lees, Eva Lester, Chooi Cheah Lim, J D Lloyd-Still, S J McDonald, Stuart McHardy-Young, Marion MacLellan, Margaret R McMinn, Margaret M McNamara, J J M Marot, June E Marrable, Harriet M C Mason, Pamela J Massie, R E May, R D G Milner, R L Mitchell, Michael Modell, M A Modelski, J F Moore, T S Morley, A E Morris, M D R Morris, J F Murray, A J H Nix, J R Norman, George Nuki, D Ajuebitsi Ogbe, P M Olley, E G J Olsen, S M Patient, H G Peters, J B Phillips, Douglas Pickering, C I Porter, A R C Ralph, Durgapursad Ramprotal, L M Razavi, R J Rew, D A Reynolds, M T Reynolds, Janet Riddle, A D Rogers, P J Y Scott, Paul Sharpstone, C M Signy, G M Slade, J K Smallshaw, M J Smith, Akanni Olufemi Olakunle Sorungbe, F B Stephenson, Mary Stewart, A E Stocks, Norma A Taylor, R G N Thomson, Reginald Tiru-Chelvam, P M J Tombleson, Madueke Ugwunze, Keith Urwin, P L H Vernon, B A Waldron, Judith G Walker, B A Wallace, P J Watt, Tessa Westcott, Myra Wharf, W F White, R W Wille, D E Williams, J G Williams, Norman Williamson, J G Wingfield, Manmohan Singh Wirk, J D Wonham, Adeline Chung Ling Yen

The following diplomas and those mentioned in our issue of Jan 23 (p 234), were conferred jointly with the Royal College of Surgeons

D A —George Chasapakis
D C H —Rabindra Nath Mukerjee
D I H —Fredoon Kaikhushro Amroliwalla, J C Cape, Jitendra Chandra Chakrabarti, Catherine J S Gauvain P A Lee, Zivojin Lukic, I A McIntosh, Vlasta Mucic, J H Neal, Akhouri Ram Nandan Prasad, R C Robb, E R Simpson, Rosemary Trewby
D P M —A K M N Chowdbury
D T M & H —T W Brown, D H Cook, Ahmad Hadjian, Tanvir Islam, Ashok Dwarkanath Laud, Lyn W Padgett, Robert Scott, Vafiuddin Shaikh, G R Thompson

Royal Society

At a meeting of this society to be held on Feb 11 at 4 30 P M at Burlington House, Piccadilly, London, W 1, Dr Elsie Widdowson, Prof R A McCance, and Mr J W T Dickerson will read papers on some effects of accelerating growth

Medical Research Council

Fellowships in Clinical Research —The Council invite applications for a further series of fellowships in clinical research, tenable at centres in the United Kingdom during 1960–61 These fellowships are open to suitably qualified medical graduates who wish to prepare for a career in clinical research

Further particulars and forms of application may be obtained from the secretary of the Council, 38 Old Queen Street, London, S W 1, with whom applications must be lodged by March 15

College of General Practitioners

Last April the North-West England faculty of the college held in Manchester a symposium on Coronary Disease in General Practice Over 750 doctors applied to attend, and the success of the venture has decided the faculty to hold another similar symposium this year It will be at the Midland Hotel, Manchester, on Sunday, April 10, with Lord Cohen of Birkenhead as chairman This year's subject is Chronic Bronchitis in General Practice

British Medical Association

Sir George Pickering has been nominated as president of the Association for the year 1963–64

Imperial Cancer Research Fund

Lord Salisbury has succeeded the late Lord Halifax as president of this Fund

Scientific Attaché in Soviet Russia

Dr D A Senior, a senior principal scientific officer on the staff of the Department of Scientific and Industrial Research, has been appointed scientific attaché to the British Embassy in Moscow His assignment covers the physical sciences, biology, medicine, and agriculture

Glasgow Royal Mental Hospital

A two-storeyed extension to this hospital at Gartnavel has recently been completed It has cost £100,000 and has 80 beds arranged in 32 single rooms and 8 six-bed dormitories On each floor there is a day-room, a quiet room for reading and writing, and a dining-room Treatment rooms, consulting-rooms, and a waiting-room for visitors are also included

Nutrition and the Elderly

The Nutrition Society will hold a symposium on this subject at St Bartholomew's Hospital Medical College, London, E C 1, at 9 45 A M on Saturday, March 19 The speakers will include Prof K J Franklin, Dr C A Boucher, Dr E Woodford-Williams, Dr Alex Comfort, Dr B E C Nordin, Dr C J Earl, and Dr J V G A Durnin Further particulars may be had from Miss D F Hollingsworth, Ministry of Agriculture, Fisheries, and Food, Great Westminster House, Horseferry Road, S W 1

Training of Mental Health Staff

The Minister of Health has sought the advice of his Standing Mental Health Advisory Committee on the training required by the staff of centres provided by local health and hospital authorities for the occupation or training of mentally subnormal persons, and the Committee has appointed a subcommittee to consider this The members include Dr J A Scott (chairman), Dr D H H Thomas, Dr J S Hamilton The secretary is Mr A G Rose, Ministry of Health, Savile Row, London, W 1

The Biochemical Society will hold a symposium on the biochemistry of mucopolysaccharides, on Saturday, Feb 13, at 10 A M , at the Royal College of Surgeons of England, Lincoln's Inn Fields, London, W C 2

Appointments

Boyd, Mary M M , M D Edin , PH D Lond , M SC N Z , M R C P , D C H , D P H , D OBST senior M O (maternal and child welfare), Cornwall
Forrest, A D , M D St And , M R C P , D P M consultant psychiatrist, Royal Edinburgh Hospital for Mental and Nervous Disorders
Foster, Gillian M , M B Leeds assistant M O and school M O , West Riding of Yorkshire (Colne Valley division)
Galloway, T McL , M B Edin , F R C P E , D P H M O H and principal school M O , West Sussex
McDonald, Robert, M B Aberd , D P H , D P M consultant psychiatrist and physician superintendent, Menston Hospital, Ilkley, Yorkshire
Neal, F E , M B Sheff , F F R , D M R T consultant radiotherapist, Sheffield National Centre for Radiotherapy and hospital clinics, Sheffield clinical area
Sarkany, Imrich, M R.C.P assistant physician (part-time consultant dermatologist), Royal Free Hospital group
Spellman, Anthony, M B Lond , D P M consultant in psychiatry, Stanley Royd Hospital, Wakefield
Stewart, K A , M B Belf , F F A R C S , D A part time consultant anæsthetist, General Hospital and Royal Infirmary, Leicester

Birmingham Regional Hospital Board

Cashmore, P C , M B Lond senior casualty officer (S H M O), Burton on Trent group of hospitals
Griffiths, Peter, M B , B SC Wales, D O part-time consultant ophthalmologist, Burton on Trent group of hospitals
Roith, A I , L R C P I , D C H , D P M consultant psychiatrist and deputy medical superintendent, Monyhull Hall, Birmingham

Births, Marriages, and Deaths

BIRTHS

Gellman —On Jan 22, at the Winnipeg General Hospital, to Dr and Mrs D D Gellman (formerly Dr Vera Armett) of Ste 307, 81, Roslyn Road, Winnipeg—a son, Andrew John

The Lancet · Saturday 13 February 1960

IMMEDIATE TREATMENT OF CEREBRAL INFARCTION

SEVEN YEARS' PERSONAL EXPERIENCE

A Barham Carter
M.A., M.D Cantab , M R C.P , D P.M
PHYSICIAN, ASHFORD HOSPITAL, MIDDLESEX

Recent years have seen a revival of interest in the treatment of cerebral infarction, and some increase in knowledge of its ætiology, pathology, and mechanics Formerly treatment had three main objects—preservation of life, prevention of nursing disasters, and rehabilitation of the disabled patient No real attempt to influence the occlusion or its effect on the brain was made until Leriche and Fontaine (1934) suggested that stellate-ganglion block might improve the blood-supply of the infarcted brain and lessen the hemiplegia, even in longstanding cases Since then this and other methods, which may involve the use of powerful and dangerous drugs, have been widely studied and employed, but the position is still far from clear, and medical opinion is sharply divided on the dangers and results of treatment.

In view of this it was decided to study all patients below the age of 80 with cerebral infarction admitted to Ashford Hospital in the 7-year period from January, 1952, to December, 1958 Owing to the generosity of my colleagues this has been a personal series, and some of these cases have already been reported (Carter 1957, 1959)

Definition and Ætiology

Cerebral infarction is here defined as an ischæmic condition of the brain, producing a persistent focal neurological deficit in the distribution of one of the major cerebral arteries Consciousness may or may not be lost, there may be an obvious embolic source, and there should be no evidence of cerebral contusion, abscess, or hæmatoma. The cerebrospinal fluid (C.S F) is almost always normal to the naked eye

For many years this condition was attributed to cerebral embolism or to cerebral thrombosis, depending on the speed of onset of symptoms and the presence or absence of an embolic source. But even this diagnosis was inferential, and what seemed a classical embolism could not always be substantiated as such at necropsy It now appears that other conditions may produce cerebral infarction.

First, in many patients it has been impossible to demonstrate any clot either on arteriography (Livingston et al. 1955) or at necropsy (Hicks and Warren 1951), though later work suggests that some small proven thrombotic lesions escape arteriographic diagnosis (Alajouanine 1957), and that at necropsy small clots are often destroyed if the brain is cut while soft (Adams 1958) Therefore to say that clotting has not occurred because no clot has been found is probably unjustifiable.

Second, considerable attention has been focused on the internal-carotid and vertebral arteries in the neck, and the effects of arterial occlusion have been extensively studied (see Symonds [1957] and Hutchinson and Yates [1957]) There seems no doubt that arterial occlusion in the neck may produce cerebral infarction without a cerebral clot.

Third, cerebral arteriosclerosis has been shown to produce a state of general cerebrovascular insufficiency which may proceed to selective ischæmia or infarction by reason of focal arterial narrowing combined with systemic hypotension (Hausman 1958) Meyer and Denny-Brown (1957) showed that in monkeys collateral circulation of the brain is at first opened up by lowering of intraluminal pressure, but when the pressure falls below the critical level of 50 mm. Hg the whole system collapses and a reversible ischæmic cerebral anoxia is converted without thrombosis or embolism to irreversible infarction. But Adams (1958) regards this as an uncommon cause of major cerebral infarction, often accepted too easily at necropsy He suggests that, if the arterial tree from aorta to the site of infarction is examined carefully, and if search is made assiduously for sources of embolism, some evidence of thrombotic occlusion of the vessel supplying the infarct will be found in the vast majority of cases

The Series

One thousand and two patients below the age of 80 were admitted to Ashford Hospital with the clinical diagnosis of " stroke " between 1952 and 1958 inclusive (table I) Of these, five hundred and ten, who were thought to have cerebral infarction, form the subject of the present inquiry The figures seem very consistent from year to year, and show that cerebral infarction accounted for just over half and cerebral embolism for less than a tenth of all " strokes"

TABLE I—CASES OF "STROKE" ADMITTED TO ASHFORD HOSPITAL, SHOWING SEX AND ÆTIOLOGY

Year	No of cases	Sex		Ætiology		
		Males	Females	Embolism	Thrombosis	Hæmorrhage
1952	140	70	70	16	54	70
1953	154	75	79	18	62	74
1954	134	59	75	15	47	72
1955	140	65	75	9	61	70
1956	140	67	73	9	63	68
1957	147	70	77	10	66	71
1958	147	72	75	8	72	67
Total	1002	478	524	85	425	492

American figures (Murphy 1954) suggest that thrombosis accounts for 65%, embolism for 5%, and hæmorrhage (including subarachnoid hæmorrhage) for 30% of all strokes Glynn's figures (1956) accord more closely with mine. Reviewing the consecutive cases of cerebrovascular disease admitted to a London general hospital during 4 years, he found that 56% had cerebral thrombosis, 36% had hæmorrhage, 3% had embolism, and 5% were undiagnosed.

Distribution and Type of Infarction

In the eighty-five cases of cerebral embolism the diagnosis was made on the very sudden appearance (often within seconds) of hemiplegia, hemianopia, or aphasia in the presence of auricular fibrillation, subacute bacterial endocarditis, recent coronary thrombosis, or mitral stenosis with sinus rhythm

Such patients may, of course, have other cerebral disorders producing neurological deficit, but when a very sudden unilateral cerebral lesion develops during the waking hours

TABLE II—CASES OF CEREBRAL EMBOLISM

Year	No of cases	Sex		Average age (yr)	Hemiplegia		
		Males	Females		Right	Left	None
1952	16	5	11	52	5	10	1
1953	18	7	11	50	6	10	2
1954	15	5	10	48	5	8	2
1955	9	4	5	53	4	5	
1956	9	4	5	56	4	4	1
1957	10	4	6	57	5	4	1
1958	8	3	5	55	3	4	1
Total	85	32	53	53	32	45	8

TABLE III—ÆTIOLOGY OF CEREBRAL EMBOLISM

Year	No of cases	Ætiology					
		Mitral stenosis +fibrillation	Mitral stenosis	Fibrillation	Cardiac infarct	Subacute bacterial endocarditis	Thyrotoxicosis + fibrillation
1952	16	8	1	2	2	2	1
1953	18	10	2	2	2	1	1
1954	15	7	1	2	4	0	1
1955	9	4	1	0	3	0	1
1956	9	5	0	0	4	0	0
1957	10	3	0	0	6	1	0
1958	8	2	0	1	5	0	0
Total	85	39	5	7	26	4	4

in a patient with a known source of potential emboli, the diagnosis of cerebral embolism seems reasonable A lumbar puncture was done in every case in an attempt to exclude a hæmorrhagic lesion

All the cases of cerebral embolism are analysed in table II, which shows that since 1954 the incidence has decreased Table III shows that the ætiology has changed also, with cardiac infarction tending to replace mitral stenosis as the commonest underlying heart lesion The distribution of infarction in the eighty-five patients with cerebral embolism was mid-cerebral in seventy-seven (thirty-two with right hemiplegia, and forty-five with left hemiplegia), posterior-cerebral in four, anterior-cerebral in one, and vertebral-basilar in three

In the four hundred and twenty-five patients with cerebral infarction not obviously due to embolism the diagnosis was based on a persistent focal neurological disorder in the distribution of one of the major cerebral arteries, in the absence of a history of head injury, and with C S F normal to the naked eye In addition there was no clinical evidence of tumour, abscess, or hæmorrhage

A differential diagnosis between cerebral thrombosis, carotid or vertebral stenosis or thrombosis, and cerebral ischæmia with atheroma but without thrombosis is often impossible clinically, because carotid occlusion may equally produce either no disability at all, or attacks of transient cerebral ischæmia before infarction, or a classical complete " mid-cerebral type " infarction without warning Similarly the infarction due to tissue anoxia associated with narrowed vessels often cannot be distinguished clinically from that due to thrombotic occlusion

To obtain some idea of the relative frequency of the three main types of cerebral infarction either arteriography during life or necropsy is necessary In this series I thought that routine carotid arteriography was unjustifiable, in view of its possible dangers, and particularly the general cerebral vasoconstriction often produced after puncture of the carotid and injection of the dye However, when there was doubt about the diagnosis either on admission or during the course of the illness, arteriography was performed the condition of two of the forty-five patients subjected to this investigation became worse Of these doubtful cases twenty-seven were found to have carotid occlusion, but many more of the whole series must have had stenosis or occlusion of the carotid or vertebral arteries

Occasionally the diagnosis was made on the history of ipsilateral recurrent visual loss with attacks of contralateral weakness affecting the arm mostly, or on the finding of a systolic murmur over the carotid opposite the C6 vertebra The pulse over the affected carotid was rarely diminished In fifty-two cases (from 1954 to 1958) a full postmortem examination of the cervical vessels was made in addition to the usual brain examination, twenty-two showed infarction with atheroma and without thrombosis, twenty had thrombus in the vessel supplying the infarcted area, and ten had cervical-carotid occlusion (complete in seven, and incomplete in three) If morbidity is proportional to mortality it seems that carotid occlusion may account for 20% of cases of cerebral infarction

The meaning of the terms used must be strictly defined and agreed " Cerebral thrombosis " has become so much a part of current medical terminology that it should, perhaps, still be used for patients with cerebral infarction, though there may be no clot and the occluding lesion may not even be cerebral " Cerebral infarction ", another possible term, is correct, but has the disadvantage of including patients with cerebral embolism The term " cerebral thromboembolism " is accepted in North America " Non-embolic cerebral infarction " (Carter 1959) is clumsy and not always correct, because a cerebral thrombus may occasionally produce subsequent infarction by distal embolism Thus it may be as well to retain " cerebral thrombosis " as the provisional descriptive term for cerebral infarction not obviously due to embolism, and to make a more accurate final diagnosis when the appropriate investigations are completed

Describing the onset and course of cerebral infarction is equally difficult For the gradual type the following terms are in current use " slow-onset stroke ", " ingravescent infarction ", " ingravescent stroke ", and " stroke-in-evolution " (Fisher 1958) The word " stroke " has caused much confusion because it is sometimes used for the neurological deficit, sometimes for the state of consciousness, and sometimes for the first symptoms of brain damage Moreover it may include all types of lesion from a hypertensive cerebral crisis, through embolism and thrombosis, to any sort of intracranial hæmorrhage Because of this confusion it would be wise to banish the word from medical terminology, as we have banished " heart attack " " Ingravescent cerebral infarction " could then be used, being defined as cerebral infarction in which the neurological deficit has not yet become absolute, and in which the onset of symptoms takes time to develop The exact time is not of great importance therapeutically, though arbitrarily over 2 hours is considered slow, and under 2 hours sudden, because in most patients the time falls well to one side of this line (Carter 1959)

TABLE IV—CASES OF NON-EMBOLIC CEREBRAL INFARCTION (CEREBRAL THROMBOSIS) SHOWING AGE, SEX, AND TYPE OF OCCLUSION

Year	No of cases	Sex		Average age (yr)	Type of occlusion		
		Males	Females		Anterior-cerebral	Mid-cerebral	Vertebral-basilar
1952	54	24	30	62	0	51	3
1953	62	30	32	65	0	56	6
1954	47	23	24	64	1	40	6
1955	61	30	31	65	1	52	8
1956	63	30	33	67	0	53	10
1957	66	34	32	64	1	56	9
1958	72	34	38	66	0	62	10
Total	425	205	220	65	3	370	52

Cerebral infarction was commonly distributed in the territory of the mid-cerebral artery, of the four hundred and twenty-five infarctions three hundred and seventy were in this group Of the other infarcts, forty were in the vertebral-basilar territory, seven patients had posterior-inferior-cerebellar-artery occlusions, five had posterior-cerebral occlusions, and three were anterior-cerebral (see table IV)

Differential Diagnosis

The most important differential diagnosis of cerebral infarction is from cerebral hæmatoma, especially when the question of anticoagulant therapy is considered

Subdural hæmatoma is less difficult to differentiate than intracerebral hæmatoma as a history of injury or fall, or fluctuation of signs—often with pupillary changes—may be helpful Some loss of consciousness is common, and the neurological deficit spreads smoothly rather than irregularly, showing greater fluctuation than arises with infarction Six patients of the present series were proved by carotid arteriography to have subdural hæmatoma, and three to have intracerebral hæmatoma

TABLE V—RESULTS OF TREATMENT IN CEREBRAL EMBOLISM (ONE CASE FROM 1957 AND ONE FROM 1958 ARE NOT INCLUDED)

Year	No of cases	Recovered	Improved	Not improved	Died	Treatment
1952	16	4	1	2	9	Repeated stellate block
1953	18	4	2	3	9	No treatment
1954	15	8	3	0	4	Single stellate block and anticoagulants
1955	9	5	1	1	2	Anticoagulants
1956	9	4	2	1	2	
1957	9	4	2	1	2	
1958	7	3	1	2	1	

Difficulty arises more often with primary intracerebral hæmatoma. This condition is easy to recognise in about 60% of cases, because the patient has a sudden attack with loss of consciousness, and the C.S.F. is bloody or xanthochromic. Hypertension is commonly severe, and, if the patient improves, headache and vomiting are prominent Improvement is followed by further decline, with signs of cerebral compression, which if unrelieved leads to death. In some patients, however, the history and course is much more like cerebral infarction, and then the clinical diagnosis becomes difficult (Elkington 1958, Kelly 1958) Anticoagulants are likely to be used for the type of infarction with a quiet ingravescent onset and little loss of consciousness, the course of which is characterised by a step-like pattern of motor or sensory loss, with sudden increase or spread of weakness to previously unaffected areas Headache is not prominent, some recovery follows within a few days, and signs of cerebral compression are absent. The patient is usually normotensive, the C.S.F. is clear, and the neurological deficit is in the distribution of one of the major cerebral arteries. Unfortunately some of these features have been found in primary intracerebral hæmatomata McKissock et al. (1959) have published their experiences with two hundred and forty-four consecutive cases of this condition, proved either at operation or necropsy They found that in 11% the onset was gradual, in 20% the C.S.F. was clear, in 23% the blood-pressure was normal, and in 46% consciousness was preserved. They also found that the accuracy of arteriography in diagnosis was below 70%

In the present series little difficulty was found in diagnosing cerebral embolism. In the case of non-embolic cerebral infarction (suitable for anticoagulant treatment) the diagnosis was accepted if all the criteria of slow onset, step-wise course, normal blood-pressure, clear C.S.F., involvement of the territory of one cerebral artery, and little loss of consciousness were present

Treatment

From 1952 to 1955 an attempt was made to assess the value of different forms of treatment, and to balance any benefit against any adverse effects These results, with details of treatment, have already been recorded in full (Carter 1957, 1959)

Briefly, cerebral embolism was considered separately from the other forms of cerebral infarction. In 1952 repeated stellate-ganglion block was used, and the results were compared with an untreated series of patients admitted in 1953 In 1954 the patients were treated by a single stellate block followed by anticoagulant therapy, and the 1955 groups by anticoagulants alone. The results (table V) showed that the patients treated by stellate block did not improve, but those treated within a week of onset by anticoagulants with or without one stellate-ganglion block showed significant improvement.

The other forms of cerebral infarction were grouped together as "cerebral thrombosis" In these patients similar methods were used, though the timing was different. In 1952 no specific treatment was given, but in 1953 repeated stellate block was used In 1954 the inhalation of 5% carbon dioxide in oxygen through a B.L.B. mask was employed for 5 minutes every hour during the first 48 hours, as this is said to produce the greatest cerebral vasodilatation with increased blood-flow (Kety and Schmidt 1948) In 1955 all patients were treated by anticoagulants in the form of heparin by injection combined with oral phenindione ('Dindevan') The results (table VI) showed that repeated stellate block produced no improvement, that carbon dioxide produced slight improvement, and that anticoagulants produced still more improvement This became significant ($P < 0{\cdot}05$) when the cerebral infarction was of slow onset and incomplete.

TABLE VI—RESULTS IN CEREBRAL THROMBOSIS CASES UNSELECTED

Year	No of cases	Recovered	Improved	Not improved	Died	Treatment
1952	54	13	12	9	20	No treatment
1953	62	14	16	8	24	Stellate block
1954	47	15	12	4	16	CO_2 inhalation
1955	61	20	16	9	16	Anticoagulants

After this experience, certain modifications were instituted during 1956–58 Stellate-ganglion block and carbon-dioxide therapy had not been of value in the treatment of cerebral infarction, and with two exceptions (cerebral embolism, and particularly ingravescent cerebral thrombosis if the paralysis was not complete) this was also true of anticoagulants

The modifications that seemed necessary were three

1 The age-limit of 80 was lowered to 70 (though occasional exceptions in the case of "young" septuagenarians were allowed) because visceral bleeding was more common in old people even with prothrombin-times only twice normal, and because of the greater difficulty in prothrombin-time control in this age-group

2. The dose of anticoagulants was reduced. In the previous years, when full doses were given to raise the prothrombin-time to four times normal, bleeding often occurred in the patients over 60, but a smaller dose seemed to produce equally good results The following method was used for all patients (a) on admission heparin 12,500 units was given intravenously with phenindione 200 mg orally, (b) two similar doses of heparin were given intramuscularly 6 and 12 hours after admission, and (c) during the second 24 hours phenindione 150 mg was given in divided doses, and thereafter sufficient to keep the prothrombin-time between two and three times normal

3 The third modification was to prolong the treatment from 2 to 4 weeks Originally 2 weeks' treatment was considered adequate, as in thromboembolism of the limb vessels, but an occasional return of symptoms in the 3rd week suggested that this was not long enough for cerebral infarction. Therefore a full 3-week course was given, followed by a 4th week of gradually reduced dosage so that the prothrombin-time did not fall too quickly

The results during 1952–55 had provided some indications for the treatment of cerebral infarction Anti-

TABLE VII—CEREBRAL THROMBOSIS RESULTS OF TREATMENT IN SELECTED INGRAVESCENT CASES

Year	Total no of cases	Anticoagulant treatment					No anticoagulant treatment				
		No of cases	Recovery	Improvement	No improvement	Death	No of cases	Recovery	Improvement	No improvement	Death
1956	24	12	6	3	2	1	12	4	2	3	3

1957	20	5	1	3	1	2	2	3	3
1958	22	5	1	3	2	3	4	3	1
Total	66	16	4	9	4	9	9	8	7

coagulants were most useful in cerebral embolism, and less so in certain types of cerebral thrombosis Early treatment was reviewed and modified During 1956–58 all patients with cerebral embolism were treated with anticoagulants unless there was blood in the C S F, unless they were over 70, and unless their diastolic blood-pressure was over 120 mm Hg Only two patients were rejected on these grounds, and twenty-five admitted in these 3 years were treated with anticoagulants The results, shown with the previous years' results in table V, are consistent

The situation was different with cerebral thrombosis because the indications for treatment were not so clear, and the contraindications were more obvious than in overt cerebral embolism Hence selection of patients for treatment during 1956–58 seemed desirable Patients with a history of onset of lesion developing within 48 hours and lasting more than 2 hours, with a diastolic pressure below 120, and with no macroscopic evidence of blood in the C S F were selected for study During these 3 years two hundred and one patients were admitted with the diagnosis of cerebral infarction, without obvious embolic source, and in sixty-six of these the onset was slow, as defined above They were divided into two equal groups, and alternate patients were treated with anticoagulants The results are shown in table VII

Results

Assessment

With few exceptions most of the neurological recovery from cerebral infarction takes place in the first 4 weeks, and very little change, apart from that due to re-education and adaptation, can be expected after 3 months Certain workers—notably Leriche and Fontaine (1934) in France—have held more optimistic views, but experience in this country is less encouraging The final assessment was made by examination 6 months after infarction, and the patients were simply divided into four groups recovered, improved, not improved, or died

" Recovered " meant that the patients noticed little or no disability and were able to resume successfully their former occupation. *Some loss of fine-movement dexterity was considered compatible* with recovery if the above criteria were fulfilled. Probably all patients with initial hemiplegia continue to show slight permanent pyramidal signs " Improved " meant that some useful movement was possible at elbow and wrist, and that the patient could get about with slight assistance " Not improved " indicated no return of arm movement below the shoulder, though some leg function was regained Almost all patients who survive infarction with hemiplegia regain some movement of the shoulder and the leg

Analysis of Results

The results in patients with cerebral embolism are recorded in table V In 1952–53 the results were good (" recovered " or " improved ") in eleven out of thirty-four patients, and this 33% recovery was unchanged by [illegible] ganglion block This compares with the usual recovery-rate of about 40% (Wells 1959) In the following years forty-nine patients were treated with anticoagulants (preceded in 1954 by a single stellate block) and in thirty-three the results were good, representing 66% These figures are significant (P=0 025), and the proportion of patients who recovered was doubled in the treated group

The results in patients with cerebral thrombosis were rather harder to assess (table VI) The natural history suggests that just about half the patients recover, about a third die within a year, and the remaining sixth are unimproved With carbon-dioxide therapy a slight improvement in these figures was obtained, and with anticoagulant therapy further slight improvement occurred so that 60% showed fairly good recovery

The usual prognostic factors, studied in all the groups, were equally distributed It soon became apparent that old age, severe and extensive infarction, prolonged unconsciousness, delay in admission to hospital resulting in dehydration and bedsores, severe hypertension, and a history of previous strokes were all bad signs The patient most likely to die was the neglected old man in poor condition with signs of longstanding ischæmic heart-disease Lesions of slow onset carried an overall better prognosis than those of rapid onset, and this improvement could be bettered by anticoagulants, particularly if the lesion had not become complete by the time treatment was begun

The results in the patients selected along the above lines during 1956–58 are shown in table VII If the " recovered " and " improved " groups are taken together, as opposed to those who died or did not improve, it will be seen that twenty-five of the thirty-three patients who were treated did well as opposed to eighteen of the thirty-three who were untreated This is 75% against 54%, and represents a just significant improvement (P=0 05)

If the patients are selected further according to the completeness or not of the lesion when treatment was begun (table VIII), greater improvement can be seen The recovery-rate in the treated " incomplete " group was 80%, and in the treated " complete " group 69% In the untreated incomplete group the recovery-rate was 50% and in the untreated complete group 53% This improvement from 50 to 80% is significant (P<0 05), suggesting that the best results will be in the patient whose lesion is slowly getting worse

Discussion

The results of this investigation suggest that the only specific treatment likely to help patients with cerebral infarction is anticoagulant treatment This has been shown to be of some value for patients with recent cerebral embolism, or with infarction of slow onset, although further selection of patients is necessary in terms of hypertension, appearance of the C S F, and age Experience has also shown that the indications have become fewer and the criteria for treatment more stringent

Mechanism of Treatment

The mechanism of anticoagulant treatment once cerebral infarction has taken place is not completely understood, but the benefit must arise in one or more of three ways Spread or propagation of clot (which sometimes occurs both distally and centrally from the original thrombosis) may be prevented, and, since this spread often involves anastomotic vessels, anticoagulants may keep the infarcted area from enlarging They may also prevent initial clot formation if the infarction were caused by atheromatous narrowing without thrombosis, combined with systemic hypotension, and they may prevent distal embolism in the case of thrombosis of large vessels This seems to be particularly useful in infarction associated with carotid and vertebral stenosis (Symonds 1957) Indeed one is tempted to suppose that the stepwise progress of ingravescent cerebral infarction is produced by repeated distal embolism, thus accounting for the curious paradox in this report—namely, that the most acute infarct from cerebral embolism and the most chronic from ingravescent cerebral ischæmia are the only types helped by anticoagulants If this is so then the comparative freedom from local hæmorrhage in this series may be put down to the fact that clinical embolism often affects healthy arteries, and distal embolism affects the smaller cerebral arteries which are known to escape atheroma. Conversely, in sudden lesions due to cerebral thrombosis the clot is presumably situated at the most unhealthy part of the vessel, and in this type of case anticoagulants have been ineffective and occasionally harmful One must also recognise that apparently adequate prolongation of the prothrombin-time will not always prevent thrombosis, and all physicians experienced in this work have known the mortifying disappointment of seeing a major thrombus strike at this time

Dangers of Treatment

The evident dangers of anticoagulant treatment, which have been rightly emphasised by most authors, are three in number The first is bleeding into and around the infarcted brain, the second is major visceral bleeding producing hypotension, and the third is the risk of treating intracranial hæmatomata with anticoagulants because of errors of diagnosis

Medical opinion is sharply divided on the possibility and extent of bleeding around or into infarcted brain Experimental work suggests that anticoagulants do considerable harm in this way

Sibley et al. (1957) showed that experimental hæmorrhagic cerebral infarcts in dogs would bleed further after the administration of dicoumarol, but when the infarcts were anæmic no such tendency was found. Moyes et al. (1957) showed that infarctions produced in dogs by injecting plastic vinyl acetate into the internal carotid artery were more hæmorrhagic in animals having anticoagulants Similarly Peterman et al. (1959) produced cerebral infarction in dogs by the intracarotid injection of blood-clot. After 3 days about half the animals were given dicoumarol, and at the end of 15 days the infarctions in the treated animals were conspicuously more hæmorrhagic and the mortality was higher

Clinically, however, the evidence against anticoagulants is less strong Fisher (1958) found no evidence that anticoagulants cause hæmorrhage into infarcted brain, and my experience (Carter 1957, 1959) agrees with this

Similarly Wright and McDevitt (1954) found no clinical evidence that anticoagulant treatment was harmful, even in hæmorrhagic cerebral infarction. Brain (1957) thinks it unwise to give anticoagulants within at least 3 weeks of an attack of cerebral infarction, and this view is supported on the Continent by de Morsier and Tissot (1957) Vastola and Frugh (1959) have reported a very disturbing series of fifty-five consecutive patients with recent cerebral infarction treated by anticoagulants There was no control series, but the authors did not think their patients showed improvement as compared with that " expected in a similar group " Twenty of the fifty-five patients bled in various parts of the body, and in four anticoagulants were blamed for extensive brain hæmorrhage—three into the infarct and one elsewhere On the other hand Wells (1959) treated with anticoagulants twenty-nine patients with 34 attacks of cerebral embolism, with results better than in his untreated series and without intracranial bleeding

Two examples will show the danger of attributing cerebral hæmorrhage to anticoagulant therapy in patients who are being treated for cerebral infarction

CASE 1 —A man, aged 67, was admitted in November, 1958, with 3 weeks' history of progressive vertigo, left homonymous hemianopia, and weakness of the legs He had had a transient right hemiparesis 12 months previously, with some personality deterioration. On the day of admission he was found lying on the floor, dazed and stuporose, with left hemiparesis Lumbar puncture showed clear C.S F under normal pressure, containing 9 lymphocytes per c.mm. and 50 mg of protein per 100 ml Next day the left hemiparesis was deeper and bilateral facial weakness had appeared. Basilar stenosis with possible thrombosis was diagnosed and anticoagulant treatment was begun. All the signs improved except the hemianopia, which remained complete.

After discharge the patient was advised to continue anticoagulants (phenindione 50 mg daily), which kept his prothrombin-time steady at about 30 seconds 6 weeks later he complained of violent headache, became rapidly unconscious, and died (the prothrombin-time was then 20 seconds) At necropsy a massive subarachnoid hæmorrhage was found, and anticoagulants were blamed until it was seen that a friable tumour, adherent to the right wing of the sphenoid, had ruptured the cavernous sinus Sections showed that this was a hitherto unsuspected cellular meningioma Basilar stenosis was present, the right posterior-cerebral artery was grossly narrowed, and the right occipital lobe showed recent softening, neither the cerebral nor cervical arteries contained thrombus

CASE 2.—A man, aged 68, was admitted in March, 1959, with an increasing left hemiparesis of 6 hours' duration. The left arm was completely paralysed, but weakness of the left leg was moderate He had no sensory loss or hemianopia. His blood-pressure was 180/115, and the C.S F was clear Anticoagulant therapy was begun. His hemiparesis improved, and he was discharged 4 weeks later, using a stick and with movement of all joints in the left arm A month later, when he was readmitted with a return of left-sided weakness, it was decided to use long-term anticoagulant therapy, and he was stabilised on phenindione 75 mg daily 4 months later he was again admitted, now moribund, and with signs of cerebral hæmorrhage. This diagnosis was confirmed at necropsy, a large hæmorrhage having destroyed the right cerebral hemisphere. The prothrombin-time of 12 seconds on the day the patient died was disbelieved, until his relatives explained that he had not taken his tablets for at least a month before his death.

The second danger of treatment—that of visceral bleeding—seemed at first a major risk, particularly in the elderly In the second half of this series, when the dosage of anticoagulants was reduced, 17 minor hæmorrhagic episodes arose in nine patients Of these hæmaturia accounted for 7, epistaxis for 5, subconjuctival hæmorrhage for 3, and facial bleeding after shaving for the other 2 In only one patient was the prothrombin-time found to be over 40 seconds, and in all the patients treatment was resumed after a 2-day interval Luckily no major visceral bleeding was encountered in the last 3 years and no patient had to be withdrawn from the treated group. Some people may bleed severely, of course, even if the prothrombin-time is not unduly raised, and the patient's condition is a more important guide than the results of blood estimations. Thus the continued use of anticoagulants is always dangerous if any visceral or serious superficial bleeding arises, even though the prothrombin-time is reasonably low.

The third danger is mistaken diagnosis. The differentiation between cerebral infarction and intracranial hæmatomata has already been discussed. Fortunately the type of infarction that can suitably be treated by anticoagulants is not the most likely to be mistaken for hæmorrhage, although a small but disturbing proportion of intracerebral hæmatomata have a slow onset without loss of consciousness, without hypertension, and with clear C.S.F. (McKissock et al. 1959), all of which are usually characteristic of infarction. But in addition the stepwise course of ingravescent infarction, and its adherence to the distribution of a major cerebral artery, are helpful in avoiding obvious error.

Indications for Treatment

Selection of patients for treatment with anticoagulants depends largely on the interpretation of the results in this series. In the first 4 years under review comparison with an untreated series suggested that vasodilators, including stellate-ganglion block, made no difference to the natural history of cerebral infarction. Short-term anticoagulant therapy improved the prognosis of cerebral embolism significantly, but not that of cerebral thrombosis, unless the patients were selected carefully. Significant improvement was obtained only if the infarction was of slow onset and the neurological deficit not apparently complete.

During the second part of the investigation the anticoagulant treatment was modified, and, in view of previous difficulties, the criteria for selecting patients were better. To test the validity of the previous years' impression, alternate patients were treated in the cerebral-thrombosis group of slow onset. The treated group improved significantly ($P=0{\cdot}05$), and this became more significant ($P<0{\cdot}05$) if the lesion was incomplete when treatment was begun. Anticoagulant treatment seems, therefore, to be indicated in all patients with cerebral embolism and in all patients with progression of cerebral infarction of over 2 hours' duration, particularly if the disability at the time of treatment is not complete. These criteria for selection of patients are subject to the overriding contraindications discussed below.

Contraindications to Treatment

Past history.—If the patient had had previous hæmatemesis or melæna, prolonged dyspepsia or proved peptic ulceration or if the control prothrombin-time was raised on admission, suggesting hepatic disease, then anticoagulants were thought to be contraindicated.

Age.—During the first 4 years of this review the age-limit for treatment was 80. In the over-70 group difficulty was experienced from time to time in controlling prothrombin-time, and superficial hæmorrhage, hæmaturia, and epistaxis were more frequent and more severe. One patient died of uræmia from hæmorrhage into the renal pelves, and another bled per rectum producing hypotension and an extension of the infarction. It was decided, therefore, that with few exceptions 70 was probably the upper limit for treatment. An arbitrary rule is obviously impossible, and after further experience this limit may be raised.

Hypertension.—Severe hypertension undoubtedly favoured a hæmorrhagic infarct or even intracerebral hæmatoma, particularly if the fundi showed hæmorrhages, papillœdema, or exudates. Renal hypertension and evidence of renal failure also seemed to promote easy bleeding. We decided arbitrarily that a diastolic blood-pressure of 120 mm. Hg should be the upper limit for anticoagulant therapy, and afterwards complications of therapy were less.

C.S.F.—Any blood or xanthochromia in the C.S.F. was regarded as an absolute bar to anticoagulant treatment, but lymphocytosis and increased protein-content (found in about half the patients) were not thought to be contraindications. Because a hæmorrhagic peripheral infarction which starts slowly will occasionally produce blood in the C.S.F., some cases of ingravescent cerebral infarction will consequently not be treated with anticoagulants. It seems reasonable, however, to suppose that the dangers of increased bleeding in this type of case outweigh any possible advantages.

Sudden onset was considered a contraindication because in the first 4 years anticoagulant treatment did not improve the natural history of this type of case. No doubt some of the patients found unconscious in their beds had ingravescent infarction, but the danger of a concealed intracerebral hæmatoma seemed too great, and they were excluded from treatment.

Unconsciousness.—In patients with cerebral embolism unconsciousness was not regarded as a contraindication to anticoagulant treatment. In the cases admitted unconscious with a lesion of slow onset it seemed unwise to give anticoagulants at once because of the possibility of cerebral hæmorrhage. If, however, consciousness was regained fairly rapidly, and then the neurological deficit began to increase, anticoagulants were thought safe unless there were other contraindications.

Conclusions

The above indications and contraindications, together with the results of this survey, suggest that anticoagulants play, on the whole, a small part in the immediate treatment of cerebral infarction. But in a select group of patients their part is important. These patients comprise those with cerebral embolism and those who remain conscious or regain consciousness quickly after the onset of cerebral thrombosis when paralysis is incomplete and worsening.

Summary

A series of five hundred and ten consecutive patients with cerebral infarction, admitted to Ashford Hospital, Middlesex, from the beginning of 1952 to the end of 1958, was studied personally.

Extracerebral vascular insufficiency was not uncommonly the cause of intracerebral infarction. In differential diagnosis it was sometimes difficult to separate cerebral infarction from intracerebral hæmatoma.

During the first 4 years of this study different methods of treatment were investigated. Vasodilator drugs and stellate-ganglion block failed to influence the natural course of cerebral infarction.

During the second half of the study anticoagulant drugs were beneficial in the immediate treatment of cerebral embolism, the follow-up period being 6 months.

Sudden and complete non-embolic cerebral infarction, particularly when accompanied by unconsciousness, was not improved by any specific treatment.

During the last 3 years of this study a controlled clinical trial was undertaken to decide whether anticoagulants would help the patient with ingravescent infarction (over 2 hours) or signs of increasing paralysis The best results were in patients who were conscious and whose lesion was incomplete when treatment was begun

It is a pleasure to thank my colleagues, Dr K D Keele and Dr J E Royds, for allowing me access to their patients, and for their valuable suggestions regarding this article

ACUTE oliguric renal failure is present when the volume of urine produced by the kidneys is insufficient for maintenance of the normal body internal environment In chronic renal failure the clinical and biochemical status of the patient may change little for long periods, sometimes for several months or even years By contrast, in acute renal failure there is progressive and continuous deterioration unless diuresis occurs or some form of dialysis is applied

The natural history of cases of acute oliguric renal failure is extremely varied because the condition may be caused by many unrelated types of disease, for example, there may be lesions of the major or minor renal arteries or veins, glomerular lesions of acute glomerulonephritis or polyarteritis nodosa, proximal tubular necrosis due to nephrotoxic drugs or poisons, ischæmic tubular lesions including acute tubular necrosis, renal cortical necrosis, acute papillary necrosis, or an acute exacerbation of chronic renal disease or bilateral ureteric obstruction

The commonest cause of acute oliguric renal failure is acute tubular necrosis, and this is singularly important because, if the patient survives, recovery is accompanied by full restitution of renal function Uncomplicated acute tubular necrosis is usually a disease of predictable course, and, if properly treated, is relatively benign When the condition is complicated by infection or by associated injuries, whether accidental or surgical, it is much less predictable and much more serious Teschan et al (1955) emphasised this difference as a result of their experience of acute tubular necrosis in the injured and wounded in the Korean campaign The course of the disease in their patients, particularly those with severe injuries to voluntary muscle, proved to be much more fulminant than in the average civilian patient without such complications A similar difference is apparent in the series of civilian cases reported recently by Parsons and McCracken (1959) and by Bluemle et al (1959) The proportion of fatal cases was less than 25% in patients in whom the acute tubular necrosis was due to medical or obstetric causes, but more than 70% when it was complicated by trauma Biochemical deterioration is more rapid in the surgical group There is frequently a dramatic rise of plasma-potassium, uncontrolled by enteral cation-exchange resins, and there is a rapid fall of plasma-bicarbonate due to uræmic acidosis In a series of 220 cases of acute oliguric renal failure of all types referred to Hammersmith Hospital for dialysis by an artificial kidney, the prognosis has been good where acute tubular necrosis was due to a medical or obstetric cause In contrast, the prognosis has been much worse in those patients in whom acute tubular necrosis was secondary to severe injuries or surgical operations A high proportion of such patients

TABLE I—RECOVERED CASES OF ACUTE TUBULAR NECROSIS

Case no	Age (yr)	Sex	Diagnosis	Duration of oliguric phase (days)	Hæmodialysis

died of their injuries or from complicating infection despite carefully controlled conservative treatment and in many cases repeated hæmodialysis

We describe here the natural history of uncomplicated acute tubular necrosis in a selected group of 28 patients in whom the primary cause of the disease was medical or obstetric (table I) All of these patients recovered completely with or without hæmodialysis This selection avoids the difficulties due to the irregular and unpredictable course when the condition is complicated by uncontrolled infection or extensive tissue damage, and permits analysis of the full course of the disease from onset to full recovery The series may be unrepresentative of all examples of uncomplicated acute tubular necrosis, since probably the more severe cases are referred to centres equipped for hæmodialysis This difficulty of sampling is, however, almost universal in descriptions of disease based on the experience of a single hospital. 5 patients with proximal tubular necrosis have been included since their course seemed to be identical with that of acute tubular necrosis

During this period deaths in cases diagnosed on admission as uncomplicated acute tubular necrosis numbered 11 (table II) 3 of these patients were proved at necropsy to have renal cortical necrosis with almost complete destruction of all nephrons The fatal cases will be described after the analysis of the 28 patients who recovered

Management

All patients were treated by a standard conservative regime The diet consisted of a 20% solution of lactose by mouth, a volume of X+400 ml daily being given from November to April, and X+500 ml daily from May to October, where X ml is the total volume of the measurable fluid loss from the patient on the previous day When intractable uræmic vomiting occurred, the same volume of sterile 40% glucose was given by infusion, preferably into the superior vena cava, but at times into the inferior vena cava, instead of by mouth Soluble insulin was given by injection when the blood-sugar was over 200 mg per 100 ml Sulphonamides or antibiotics were given only in cases with established infection, but all patients were isolated and standard methods of barrier nursing were used Infusions of packed cells were given in amounts large enough to maintain the hæmoglobin concentration above 10 2 g per litre (70% Haldane) Non-virilising androgens in the dosage recommended by McCracken and Parsons (1958) were given to the female patients during the latter half of the series Blood-urea and plasma potassium and bicarbonate were measured daily, and electrocardiography was performed daily throughout the whole of the oliguric stage Hæmodialysis was carried out by a rotating-drum artificial kidney when any one of the following indications was present (*a*) blood-urea above 400 mg per 100 ml , (*b*) plasma-bicarbonate below 12 mEq per litre, (*c*) plasma-potassium above 7·5 mEq per litre, despite therapy with cation-exchange resins by mouth (Elkinton et al 1950, Evans et al 1953), (*d*) electrocardiographic evidence of intraventricular block with widening of the QRS complexes from hyperkalæmia, (*e*) uræmic stupor, coma, vomiting, hiccough, or fits

Appropriate supplements of sodium and potassium salts were given in the diuretic stage, usually in amounts equal to the urinary losses of the previous day A diet of carbohydrate alone was continued until the blood-urea fell below 100 mg per 100 ml , unless the patient became extremely hungry and demanded solid food

Stages

The course of the disease, as suggested by Bull et al (1950), has been divided into an onset stage, oliguric stage, early diuretic stage, late diuretic stage, and convalescent stage, but the definitions of the five stages adopted here are more precise and better adapted for clinical use

Onset stage—This is the short period between the acute event causing the renal damage and the development of

TABLE II—FATAL CASES OF ACUTE TUBULAR NECROSIS AND RENAL CORTICAL NECROSIS

Diagnosis and case no	Age (yr)	Sex	Diagnosis	Stage of illness at death	Hæmo-dialysis	Postmortem findings
Acute tubular necrosis						
1	38	F	Induced abortion at 24 weeks, terminal septicæmia	10th day diuretic phase	+	Multiple hæmorrhagic abscesses (lungs, kidneys, heart, and brain), renal tubular *necrosis*
2	37	F	Induced septic abortion at 12 weeks, pelvic cellulitis	13th day oliguric phase	–	Purulent pericardial effusion with myocardial abscess, pelvic peritonitis, renal tubular necrosis
3	29	F	Induced septic abortion at 16 weeks, pelvic peritonitis	10th day oliguric phase	+	Ruptured uterus with general peritonitis, renal tubular necrosis
4	23	F	Induced septic abortion at 18 weeks	6th day diuretic phase	+	Renal tubular necrosis, septicæmia with pyodermia
5	75	F	Sensitivity reaction to sulphonamides	14th day oliguric phase	–	Renal tubular necrosis, no evidence of glomerulitis
6	54	M	Overdose of morphine with hypotension, staphylococcal pneumonia	Late diuretic phase—blood-urea 100 mg per 100 ml	– –	Lung abscess with empyema, healed renal tubular necrosis
7	61	M	Pneumonia, hypotension	2nd day oliguric phase	–	Hæmorrhagic pulmonary œdema, no evidence of pneumonia, *renal tubular* necrosis
8	57	M	Acute tubular necrosis due to pancreatitis	17th day oliguric phase	++	Renal tubular necrosis, hæmorrhagic pancreatitis
Renal cortical necrosis						
9	35	F	Concealed accidental hæmorrhage at 28 weeks, cerebral hæmorrhage	9th day oliguric phase	+	Symmetrical renal cortical necrosis, cerebral hæmorrhage
10	32	F	Concealed accidental hæmorrhage at 32 weeks, staphylococcal septicæmia	19th day early diuretic phase	+	*Symmetrical cortical necrosis of kidneys*
11	35	F	Concealed accidental hæmorrhage at 27 weeks, septicæmia	18th day oliguric phase	++	Symmetrical renal *cortical necrosis*

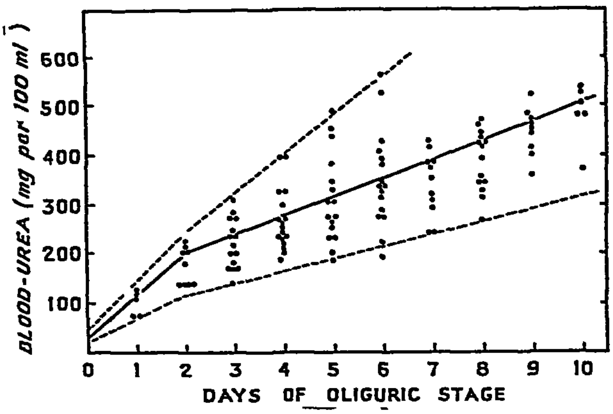

Fig 1—The rise of blood-urea during the oliguric stage of acute tubular necrosis before hæmodialysis or in undialysed patients

The rate of rise of blood-urea is greater in the first two days The regression line is calculated from days 2 to 7 inclusive, as after day 7 many of the higher blood-urea values have been reduced by hæmodialysis

established oliguria with a urine output in an adult patient of less than 400 ml per day

Oliguric stage—This is the interval between the onset stage and the first day when the urine volume is consistently more than 400 ml per day

Early diuretic stage—This is the period between the end of the oliguric stage and the first day when there is an unequivocal and sustained fall of the blood-urea

Late diuretic stage—This is the period between the end of the early diuretic stage and the first day on which the blood-urea is consistently lower than the upper limit of normal—i e 45 mg per 100 ml.

Convalescent stage—This is the period in which, although the blood-urea is normal, the patient is still unable to engage in normal activities or duties

In this account of the clinical course of uncomplicated acute tubular necrosis, the daily urine volume and the values of blood-urea are considered to be the two most important biochemical indices Although concentrations of plasma potassium and bicarbonate are of especial value in assessing the need for hæmodialysis, they may both be influenced by relatively minor therapeutic procedures such as the administration of cation-exchange resins or infusions of sodium lactate. Their values do not necessarily therefore reflect the course of the disease In contrast, the blood-urea will rise continuously unless spontaneous diuresis occurs or hæmodialysis is applied.

Onset Stage

Since all patients were referred from other hospitals early in the oliguric stage there was unfortunately no opportunity to study the patients in this important stage of the disease

Oliguric Stage

Complete anuria is extremely rare in acute tubular necrosis Urethral catheterisation was avoided in order to prevent infection, and it is therefore impossible to give the precise urinary volume produced during each day of the oliguric stage The calculated mean daily volume during the first six days was 75 ml and the mean of the whole oliguric stage was 150 ml, suggesting a slow increase of urinary volume during this stage of the disease

The mean duration of the oliguric stage was 12 5 days (S.D 5 0 days), which is similar to the mean duration reported by Bull et al. (1950) and Swann and Merrill (1953) The rate of rise of blood-urea was greater during the first two days of the oliguric stage than in the succeeding days (fig 1), the mean blood-urea rising to 200 mg per 100 ml by the end of the second day This probably reflects a temporary increase of catabolism with a greater production of urea by breakdown of tissue proteins due to the initial insult In addition, the rate of loss of urea in the small amounts of urine produced and in sweat, vomit, and fæces is roughly proportional to the concentration of urea in the blood After the second day, the rate of rise of blood-urea was reduced by treatment, and averaged 34 mg per 100 ml per day In some patients the rate of rise of blood-urea was not greater than 25 mg per 100 ml per day, which represents the theoretical minimum assuming a low endogenous protein breakdown of 40 g per day (Gamble 1951) In 3 patients the rate of rise of blood-urea was unusually great and hæmodialysis was required early in the oliguric stage 1 patient had an acute hæmolysis due to arsine poisoning, another had severe staphylococcal pneumonia, whilst the 3rd had leptospirosis with considerable liver damage. In all 3 cases there was probably an increased rate of protein breakdown from the associated condition

Of the 28 patients 13 were treated by hæmodialysis 11 had a single treatment, and 2 were dialysed on two occasions After the fifteen dialyses (twelve in the oliguric stage and three in the early diuretic stage) the subsequent daily rise of blood-urea continued unchanged (fig 2) Hæmodialysis causes the biochemical changes to revert to those found earlier in the oliguric stage, and has no other influence on the course of the disease. The rate of rise of blood-urea on the first day after hæmodialysis is usually greater than on succeeding days (fig 2) This probably reflects equilibration of the relative excess of urea in the intracellular compartment with that in the extracellular fluid and plasma The artificial kidney clears urea first from the blood and extracellular fluid.

Early Diuretic Stage

Division of the diuretic stage into an early and late stage is of great clinical value because the amount of urea excreted during the early diuretic stage is approximately equal to that formed from endogenous protein breakdown, and there is usually no fall of the blood-urea Indeed, during the early diuretic stage the clinical and biochemical

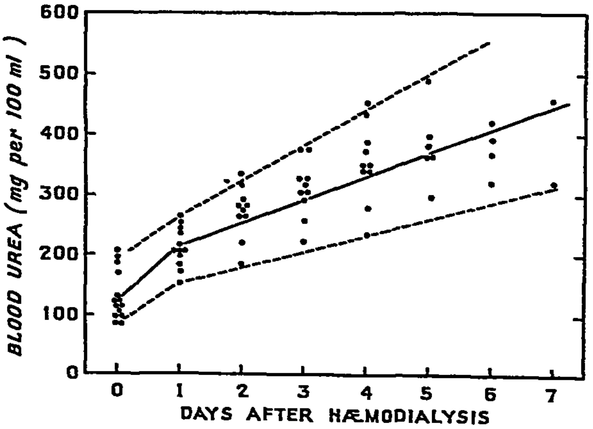

Fig 2—The rise of blood-urea during the oliguric stage of acute tubular necrosis after hæmodialysis

The rate of rise is greater on the first day after dialysis Subsequently the mean rise is identical with that shown in fig 1

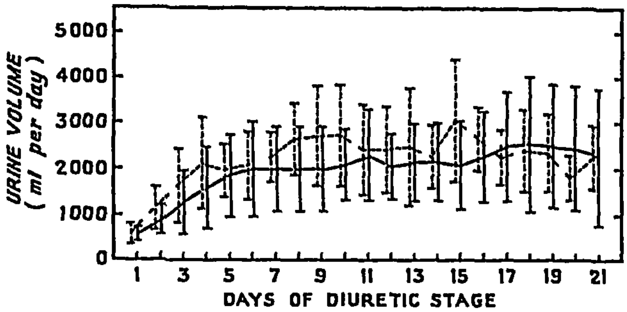

Fig 3—Urinary volume per day in the diuretic stage of acute tubular necrosis Continuous lines show the results from the present series, interrupted lines the results of a similar series treated by Bull et al with a greater fluid intake during the oliguric stage, with mean and standard deviations in each case

The mean volume in the series of Bull et al is consistently greater until the 17th day of the diuretic stage

status of the patient does not improve and frequently continues to deteriorate In the late diuretic stage, however, when the blood-urea falls, there is steady and progressive improvement Hæmodialysis may have to be carried out in the early diuretic stage, but is rarely, if ever, indicated in the late diuretic stage As soon as the daily urinary volume consistently exceeds 400 ml there is usually a steady daily increase at a mean rate of 280 ml per day until a volume of about 2000 ml per day is reached after five or six days (fig 3). Thereafter the mean daily urinary volume is stabilised at 2000–2500 ml The mean duration of the early diuretic stage was 4 7 days (S D 3 1), and stabilisation of the urinary volume roughly coincided with the day on which the blood-urea started to fall

Late Diuretic Stage

Urine volumes in the late diuretic stage are now less than in cases treated ten to twelve years ago (Bull et al 1950) It was then customary to give patients more fluid during the oliguric stage—usually 1000 ml more than the total fluid loss on the previous day In fig 3 the mean urinary volumes in the present series are compared with those in a similar series of cases of acute tubular necrosis reported by Bull et al (1950) The mean urinary volumes are consistently higher in the latter series until the seventeenth day of the diuretic stage ($\chi^2=95$, $P<0\ 001$) If it is assumed that the patients of Bull et al received an excess fluid intake of 500 ml each day during the twelve days of the oliguric stage, the average total excess given to each patient was 6 litres Comparison of the urinary volumes in fig 3 shows that the patients of Bull et al, on an average, each excreted 6 5 litres more urine than the patients of the present series during the first seventeen days of the diuretic stage This suggests that the greater diuresis in the patients of the earlier series was largely due to the higher fluid intake during the oliguric stage It has been claimed (Black 1957) that high urinary volumes in the diuretic stage of acute tubular necrosis are chiefly due to osmotic diuresis, the osmotic load per single functioning nephron being abnormally high The observations recorded here suggest, however, that at least part of the diuresis in patients treated in the past was due to water diuresis from prior over-hydration Whereas an individual with normal renal function would excrete an excess body-water content of 6 litres within twenty-four hours, a patient in the diuretic stage of acute tubular necrosis has gross impairment of renal function (Swann and Merrill 1953) and requires over two weeks to excrete excess water which could be eliminated by healthy kidneys within a single day An excess body water content of 6 litres is equivalent to 13% of the normal total body-water and could cause considerable water intoxication

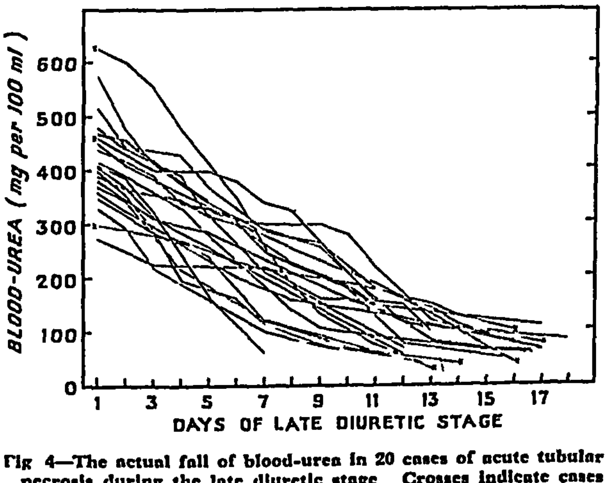

Fig 4—The actual fall of blood-urea in 20 cases of acute tubular necrosis during the late diuretic stage Crosses indicate cases by hæmodialysis

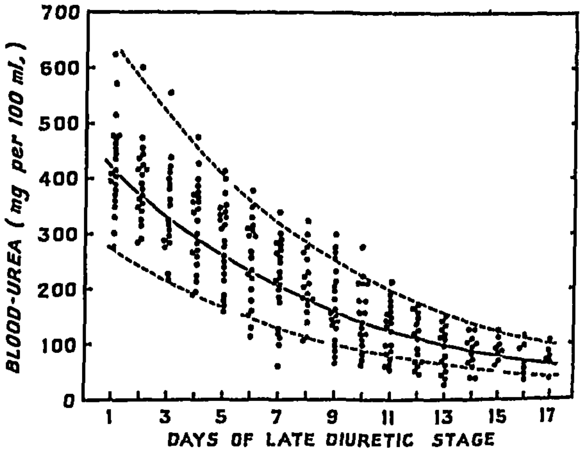

Fig 5—The fall of blood-urea during the late diuretic stage of acute tubular necrosis The logarithmic regression-line and limits at twice the standard deviation are shown

During the late diuretic stage there is a progressive exponential fall in the blood-urea (figs 4 and 5) On an average, the blood-urea becomes normal within seventeen days (fig 5)

Convalescent Stage

By the end of the late diuretic stage the patient has passed through a long and serious illness which has lasted on an average five weeks (fig 6) During this period there has been little or no intake of protein Although modern conservative therapy reduces endogenous protein breakdown, often to a value as low as 40 g per day, five weeks of protein starvation causes a loss of at least 1 5 kg of body-protein—about an eighth of the total body content The majority of this endogenous protein is derived from voluntary muscle The patient at the start of the convalescent stage is still an invalid, characteristically weak and often unable to stand or walk unaided Further recovery, however, is very rapid, the patient usually develops an insatiable appetite and quickly gains weight with increase of muscle mass and restoration of muscle

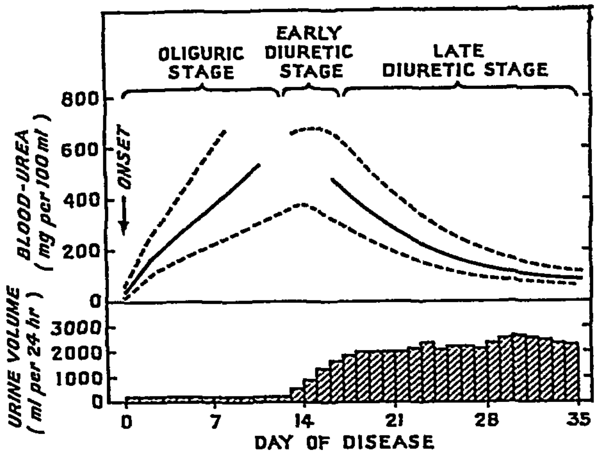

Fig 6—Graphical representation of an average case of acute tubular necrosis which summarises the previous charts.

The regression-lines of blood-urea and the upper limit at twice the standard deviation for the oliguric and late diuretic stages are not continuous in this series, because many of the patients were treated by hæmodialysis in the last few days of the oliguric stage

strength Usually it is at least two or three months from the start of the illness before the patient is well enough to resume full activities and duties

CLINICAL COURSE OF FATAL CASES

Of the 11 fatal cases (table II) originally diagnosed as uncomplicated tubular necrosis, all were examined at necropsy 3 cases, all due to concealed accidental hæmorrhage of pregnancy, were found to have had severe bilateral renal cortical necrosis causing irreversible renal damage We prefer to avoid percutaneous renal biopsy during the oliguric stage of acute renal failure, and therefore have no means of differential diagnosis between renal tubular necrosis and renal cortical necrosis except the response to therapy The apparent mortality in this series was therefore 28%, but the true mortality excluding the cases of renal cortical necrosis was 22%—a figure similar to those in other reported series

Of the 8 fatal cases of acute tubular necrosis, 4 died in the oliguric stage, 2 in the early diuretic stage, and 2 in the late diuretic stage They showed no obvious biochemical differences from the patients who survived, and the oliguric stage of the 4 patients who died in the diuretic stage was not unusually long Table II shows that sepsis, usually from organisms resistant to most available antibiotics, was the main cause of death

Of the 3 fatal cases of renal cortical necrosis 2 also died as a direct result of infection, although the severity of their renal lesion would have precluded final recovery 2 of these 3 patients died in the oliguric stage, on the ninth and eighteenth days The 3rd patient passed into an early diuretic stage on the twentieth day of her illness, and the urine output rose to a maximum of 970 ml per day before death on the twenty-ninth day This shows that a guarded prognosis should be given in all cases of acute oliguric renal failure due to concealed accidental hæmorrhage of pregnancy, unless the patient has passed into the late diuretic stage with a steadily falling blood-urea Even if percutaneous renal biopsy in such cases showed only acute tubular necrosis, this would not preclude renal cortical necrosis in other parts of the kidneys

Discussion and Summary

The average course of uncomplicated acute tubular necrosis is summarised in fig 6 Average durations of the first four stages of the disease are plotted on the abscissa, and the blood-urea and mean urinary volumes on the ordinate The regression-lines for blood-urea and the upper limits at twice the standard deviation for the oliguric and diuretic stages are not continuous because almost half the patients were dialysed at the end of the oliguric stage Hæmodialysis artificially reduces the blood-urea at the start of the early diuretic stage It is almost certain that some of the patients would not have survived had hæmodialysis not been applied Since the rate of climb of the blood-urea during the oliguric stage is identical before and after dialysis (figs 1 and 2), it is permissible to extrapolate the rise of blood-urea after dialysis to that before treatment in order to estimate the eventual level had dialysis not been carried out. In the 2 patients who required dialysis on two separate occasions, the blood-urea would have been expected to rise to 1020 and 1110 mg per 100 ml Although in isolated cases recovery has followed the recording of similar levels of blood-urea, most such patients will die without hæmodialysis

This paper may prove useful to those responsible for the decision to transfer cases of acute tubular necrosis to a centre with facilities for hæmodialysis Although the duration of the oliguric stage in any single case remains unpredictable, the course of the oliguric stage may be accurately predicted after only a few days' careful observation The course of cases with severe tissue damage cannot be predicted Deterioration may be extremely rapid, and in these cases a high plasma-potassium or a low plasma-bicarbonate may provide urgent reasons for hæmodialysis before the blood-urea exceeds 400 mg per 100 ml

Thanks are expressed to Prof G M Bull for permission to publish urinary volumes of patients under his care, and to Prof J McMichael and Prof E J King for advice

CRYPTOGENIC LIVER ABSCESS

J F Stokes
M D Cantab , F R.C.P
PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL, LONDON, W C.1

Liver abscess is uncommon in Great Britain Between 1950 and 1958 only 8 cases have occurred in 14,500 admissions to the Hospital for Tropical Diseases (U C H), giving an incidence of 0 055% All these were shown to be amœbic in origin

With a chronic abscess in a patient at risk for amœbiasis it is sometimes difficult to be certain whether amœbæ were initially responsible for it and whether their presence has been obscured by superadded bacterial infection There is a growing feeling, however, that pyogenic infection is becoming more important as a primary cause even in tropical practice (Worms 1956), and this is supported by McFadzean et al 's (1953) figures from Hong Kong

During the decade 1949–58, 6 cases of liver abscess have been seen in 183,000 admissions at University College Hospital in the general wards and in my private practice, giving an incidence of 0 003% None of these patients was at risk for amœbiasis, no amœbæ were found in any case, and it seems certain that they were pyogenic in origin This incidence agrees with de Bakey and Creech's (1956) estimate of 0 04–0 007% of all hospital admissions

Pyogenic organisms may gain access to the liver

1 From outside the body by trauma, which is self-evident

2 Via the hepatic artery, in which case systemic blood-culture should be positive

3 Via the bile-duct, when prominent early jaundice is to be expected

4 Via the portal vein In this group primary disease in the alimentary tract may be demonstrable (Dieulafoy 1898, Ochsner et al 1938, Shallow et al 1945, Champeau 1956), and a consideration of the venous drainage alerts the doctor to the possibility of hepatic spread

Diagnostic difficulty arises when no primary lesion is apparent and the liver abscess itself produces the presenting symptoms 4 of the 6 cases seen in the past decade fall into this group

Case-records

Case 1 —A 78-year-old lady developed malaise, nausea, and vomiting on April 27, 1957 She had had appendicectomy for recurrent lower abdominal pain many years before, and had also suffered from cataract and allergic rhinitis, and had bilateral operations for carpal-tunnel syndrome She was afebrile and there was no alteration in bowel habit, though other members of the household had recently had gastroenteritis

When seen on May 4 she was mentally confused and clinically anæmic Upper abdominal pain had appeared and there was slight tenderness across the epigastrium but no other abnormal physical signs During the next fortnight fever appeared and she developed a leucocytosis of 20,000 (90% neutrophils) Her hæmoglobin fell from 88% to 70% The erythrocyte-sedimentation rate (E S R) was 52 mm in first hour (Westergren) Blood-culture was sterile Liver dullness was increased, though the edge of the liver was never palpable, and movement of the right diaphragm became reduced. X-rays showed a high right diaphragm and an enlarged liver shadow She was never jaundiced Her confusion increased to such a point that lumbar puncture was performed (demonstrating a normal cerebrospinal fluid) and a psychiatric opinion was taken before a diagnosis of liver abscess was made

After preliminary treatment with penicillin and streptomycin, the upper part of the right lobe of the liver was explored on May 23 after resection of the 12th and 11th ribs A soft area was found from which thin yellow offensive pus was aspirated An abscess 2 × 2 in was drained. Moderate numbers of gram-positive cocci and bacilli were seen in a smear of the pus, and it was thought that the lack of significant growth on culture after seven days indicated that these organisms were probably delicate anaerobes

Her confusion disappeared and she made an uninterrupted recovery She has since remained well

Case 2 —A publican's 33-year-old wife had complained of right-sided abdominal pain for six weeks before she was seen on May 7, 1957 During this time she had been febrile on and off and feeling generally unwell Her waist measurement had increased by 2 in though her weight had decreased She remembered having had a short attack of lower abdominal discomfort and diarrhœa four months previously, but her bowels had always been erratic. She had previously suffered from asthma and neurodermatitis and was highly strung

She was ill and clinically anæmic, and there was muscular guarding and some tenderness in the upper abdominal quadrants, especially on the right, but there were no other abnormal signs Her urine contained no pus and was sterile Hæmoglobin 72% White cells 10,400 (69% neutrophils), E S R. 54 mm in first hour

She declined admission to hospital till June 10, when her temperature had risen to 105° She was very ill, the area of liver dullness was enlarged, but no liver edge could be felt She became very slightly jaundiced (serum-bilirubin 1 8 mg per 100 ml) and the urine contained bilirubin A few rales appeared at the right lung base and she was treated with penicillin and streptomycin Flocculation tests were normal and blood-culture sterile.

She improved temporarily and her jaundice disappeared, but persistent pain, localising tenderness, increasing leucocytosis, and falling hæmoglobin (55%) led to a diagnosis of liver abscess in the anterior part of the right lobe X-rays showed some elevation of the right diaphragm and enlargement of the liver shadow This abscess was drained per abdomen in July, 1957, but she had a stormy postoperative course and further drainage was necessary twice

Sinograms showed that the abscess extended high up into the anterior part of the right lobe (figs 1 and 2) The pus grew a microaerophilic streptococcus and *Streptococcus fæcalis* After the second recurrence of the abscess she was treated with prednisone in addition to appropriate antibiotics because the antibiotics might not be reaching the abscess cavity, her general condition had by this time improved a great deal and she was regaining her lost weight On the tenth day of this treatment she had a brisk hæmatemesis which demanded transfusion, and a barium meal showed a large gastric ulcer half-way down the lesser curvature, this did not communicate with the abscess and had given no previous symptoms Prednisone was stopped and she made a slow, steady recovery Intravenous cholangiography with iodipamide methylglucamine ('Biligrafin') showed a normal biliary tract She has since remained well

Case 3 —A 74-year-old lady had been well until an unexplained attack of diarrhœa, probably infective, at the age of 71 When first seen on Oct 7, 1958, she complained of anorexia, malaise, and fatigue for ten days, and pleuritic pain in the right lower chest for three days She was ill and anæmic but not jaundiced There were signs of aortic stenosis but no congestion of neck veins, though there was pitting œdema of both legs up to the knees Liver dullness was increased, but the liver edge was not definitely felt and was not tender There were signs of a small right pleural effusion and a friction rub high in the right axilla Her temperature was 100°, hæmoglobin 52%, and white cells 15,000 (88% neutrophils) E S R 76 mm in first hour X-rays showed a high right diaphragm and a small right pleural effusion which contained many white cells, predominantly lymphocytes, and was sterile

She was transfused but remained very ill till Oct 24, when she coughed up 100 ml of foul-smelling pus which grew an

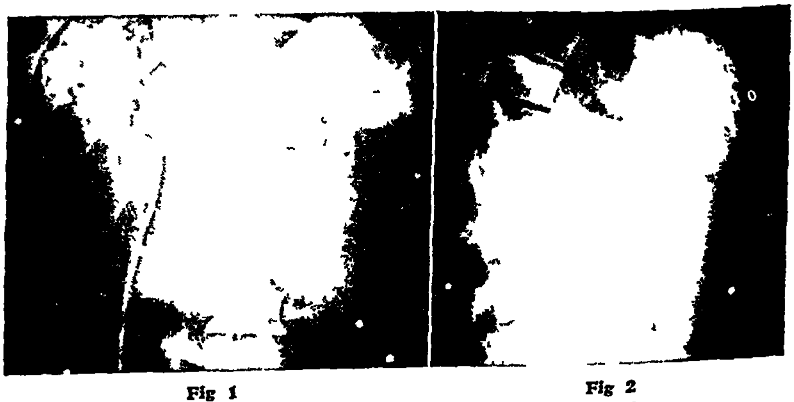

Fig 1 Fig 2

Fig 1 (case 2)—Sinogram Postero-anterior view showing abscess cavity

Fig 2 (case 2)—Sinogram Lateral view showing position of the abscess cavity in the anterior part of the right lobe of the liver

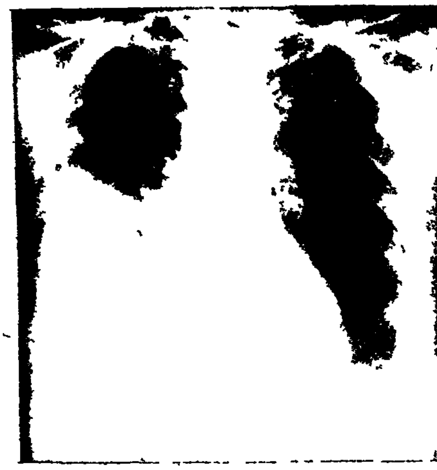

Fig 3

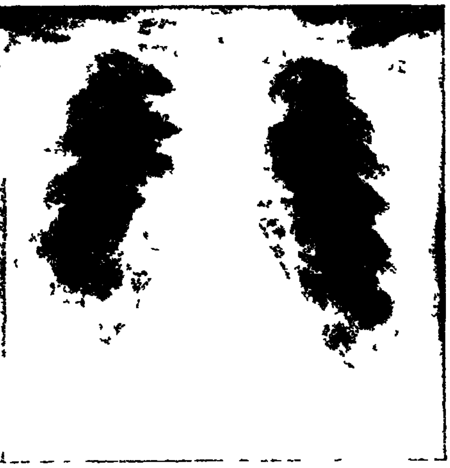

Fig 4

Fig 3 (case 3)—Postero-anterior view of chest on Oct 31 after the abscess had burst into the lung

Fig 4 (case 3)—Postero-anterior view of chest showing some residual shadowing in the right lower lobe with return of the diaphragm towards the normal position

anaerobic streptococcus It grew no tubercle bacilli and contained no cancer cells or amœbæ. She was treated with penicillin and streptomycin and postural drainage and became afebrile on Oct 31 (fig 3) Mental confusion, which had been a feature of her illness, gradually lessened and she made a slow, steady recovery, leaving hospital on Nov 23

When last seen on March 3, 1959, she had recovered her normal energy and was leading a very active life Her hæmoglobin was 84% A few râles could still be heard at the right base and the X-ray had not completely cleared (fig 4) She had no cough but she probably has some residual fibrosis in the right lower lobe She remains well

Case 4 —A 61-year-old man had had an appendicectomy at 19 and had then remained well (apart from an attack of urinary infection at 58) till he developed fever, malaise, and anorexia in July, 1955 There was a slight pleural reaction at the right base and a leucocytosis of 19,700 (84% neutrophils) He recovered after a month in hospital but had to be readmitted on Nov 11, 1955, because of malaise and upper abdominal pain. The liver was enlarged and tender, and over the next three weeks a mass continuous with the liver appeared in the right loin. Laparotomy showed this to be a large abscess in the right lobe of the liver, offensive pus, which grew anaerobic cocci, was drained through the loin. He made an interrupted recovery on penicillin and streptomycin and returned to work two months later

Discussion

Pathogenesis

From the clinical standpoint all these abscesses were cryptogenic, though in retrospect there may have been slender clues to their site of origin in the diarrhœa previously sustained by case 2 and in the gastroenteritis of other members of the household of case 1

de Bakey and Creech (1956) thought that about half of all pyogenic abscesses are cryptogenic Rothenberg and Linder (1934) believed that they are caused by hæmatogenous spread from unrecognised distant systemic foci, while Beaver (1931) regarded them as the result of quiet infection in areas drained by the portal tract The presence of anaerobic cocci in my four cases supports Beaver's concept, and it seems possible that intercurrent gastrointestinal infection can allow increased entry of gut bacteria into the portal system through an inflamed intestinal mucosa—these organisms occasionally gaining a foothold in the liver despite its liberal network of vascular anastomoses and abundant supply of phagocytes

Diagnosis

Bourne (1954) has emphasised the importance of early diagnosis if high mortality is to be avoided

Liver abscess should be suspected wherever there is fever of obscure origin accompanied by steady upper-abdominal pain Examination will show enlargement of liver dullness, even though the liver edge may not be palpable With an abscess in the upper part of the right lobe, the lower margin of the liver may be displaced downwards without becoming harder, and in determining the palpability of the liver edge firmness is more important than enlargement There may be tenderness over the liver and pain may be produced by percussion over the right lower ribs or by firm pressure in the intercostal spaces in this region Jaundice is absent, or slight and transient, as would be expected from a focal lesion of the liver not obstructing the main bile-ducts By the same token there is no indication, clinical or biochemical, of hepatocellular failure Mounting leucocytosis and a high right diaphragm afford supporting evidence, and, if the disease is firmly established, anæmia may follow

Mental confusion may be prominent in older patients This is a symptom which may be encountered in anyone of an advanced age with an acute infection, especially if he is anæmic. It deserves special mention since it was a leading symptom in case 1

If diagnosis is delayed, the abscess may rupture into neighbouring organs—most often into the lower lobe of the right lung or pleural cavity as in case 3

Treatment and Prognosis

Antibiotic treatment must be combined with adequate drainage Ideally the organism should be cultured and its sensitivity determined, in this context the importance of anaerobic culture has been stressed in general by E J Stokes (1958) and in particular by Worms (1956) In practice, these cryptogenic abscesses so often yield anaerobic or micro-aerophilic cocci that penicillin and streptomycin, to which they are commonly sensitive, should not be withheld from an ill patient

Surgical rather than spontaneous drainage is desirable Ochsner et al (1938) found that rupture into neighbouring organs worsened the prognosis, and the fatality-rate in their series, if such complications were excluded, was 36%, contrasting with the 50% rate estimated by Eliason (1926) for all cases in pre-antibiotic days

The direct benefit of antibiotics and the greater safety they confer on surgical procedures are responsible for the better prognosis in these abscesses nowadays Case 2 had much the stormiest passage and this can be related to the position of the abscess in the liver (fig 2), which demanded transperitoneal anterior drainage Ill recumbent patients cannot drain their abscesses anteriorly, and a posterior approach is preferable whenever possible

Summary

Four cases of cryptogenic non-amœbic liver abscesses with recovery are described.

No primary source of infection was evident clinically Anaerobic cocci were isolated from the pus in each case An origin in the gut and spread via the portal vein is probable

The organisms were all sensitive to penicillin and streptomycin Recovery is attributed to the use of these drugs combined with effective drainage

My thanks are due to Dr E E Pochin for access to the records of case 4

MANY attempts have been made to prepare bacterial vaccines for the prevention or attenuation of the common cold Their use has been based on the assumption that the stage of secondary infection might thereby be eliminated or reduced in severity Most of these vaccines have been prepared from mixtures of selected organisms, chosen because of their supposed pathogenicity

Of the numerous trials of such vaccines, the few in which controls were adequate have given disappointing results

Diehl et al (1938) made a carefully controlled study of three vaccines, one administered subcutaneously and two orally, with randomly selected controls receiving a placebo The group which received the subcutaneous vaccine had 25% fewer colds per person than the control group, but the groups receiving oral vaccines showed no advantage over the controls Diehl et al concluded that the vaccines had little or no practical value *McGee et al (1944), in a well-controlled trial* of two vaccines administered parenterally and three oral vaccines, found no clear evidence of a reduction in either the frequency or the severity of the common cold

In 1958, however, Ritchie reported a controlled trial in which autogenous bacterial vaccines reduced the severity of colds and the time lost from work due to colds and upper-respiratory infections in a group of factory workers Throat and nose swabs and specimens of saliva were collected from all volunteers When the subject was included in the randomly selected group to be given vaccine, the vaccine was prepared from the whole *mixed culture* of these specimens, when he was to be a control the specimens were discarded and he was given injections of carbol saline instead Injections were given weekly for up to five months during the winter, but for administrative reasons about half the volunteers stopped having injections after 8 weeks, although records of their colds continued to be made to the end of the trial The numbers of colds in the inoculated and control groups were similar, but in the vaccinated group only 13% of colds passed from the prodromal to the fully developed stage, compared with 62% in the control group There was evidence, however, that those who did not continue with the injections lost fairly rapidly the resistance which they had acquired

These findings, if substantiated, might be of considerable importance to certain groups such as flying personnel in the Royal Air Force in whom the duration and severity of colds is a matter of concern It was decided, therefore, to conduct a trial in the R A F based on Ritchie's method, but modified to meet the practical demands of the situation The vaccines were prepared in the same way as Ritchie had prepared his, but the dosage schedule was modified, as weekly injections would not be welcomed by healthy men and would be difficult to arrange on an operational flying station Furthermore there seemed to be no theoretical reason why weekly injections should produce a better immunological response than a more usual course In addition to those receiving individual autogenous vaccines and a control group given phenol saline, a third group was given a " pool " vaccine prepared by mixing the culture washings from all the members of the group

Clinical and Laboratory Methods

Selection of Subjects

The trial took place between October, 1958, and the end of March, 1959, at R A F College, Cranwell, and at R A F Stations Oakington and Thorney Island Volunteers were obtained from among flying cadets and instructors, since they would be keen to cooperate in a measure which might help to keep them flying, and because they are kept under close medical supervision, particularly with regard to respiratory infections The importance of reporting all colds, however minor, to the medical officer before flying is constantly stressed and therefore complete records could be hoped for About a dozen non-flying officers were also included, but they were treated for the purposes of the trial as if they had been fliers All volunteers were told that some of them would receive a vaccine which might reduce the loss of flying-time due to colds and that some would receive an inert control, but that they would not know till after the trial which they had received

Method of Vaccine Preparation

A single swab was used to sample the tonsillar region and the front of the mouth of each man The swabs were inoculated over the whole of a blood-agar plate After overnight aerobic incubation at 37°C the plates were inspected Eight of those allocated to the autogenous-vaccine group and nine of those in the pool group showed a heavy growth of hæmolytic streptococci, to lessen the risk of reactions, men yielding these cultures were transferred to the control group and replaced in the appropriate vaccine group by randomly selected men whose cultures did not show hæmolytic streptococci The growth on each plate from the men in the two vaccine groups was then washed off with normal saline containing 0 5% phenol and diluted separately with the phenol-saline to an opacity corresponding to a strength of about 500 million per ml A pool vaccine was constituted in the same way by mixing the washings from all the men in the appropriate group The vaccines were heated in a water-bath to 60°C for 1 hour and each was tested for sterility by inoculating 0 5 ml into a tube of thioglycollate broth. The vaccines and the phenol saline were put into individual exactly similar vaccine bottles for each volunteer.

---

* Attached to the Central Public Health Laboratory

Inoculation Procedure

A total of 320 volunteers was allocated to the groups to receive autogenous vaccine, pool vaccine, or phenol saline, by reference to a table of random numbers. Each group was treated in an exactly similar manner. Neither the volunteer nor the medical officer giving the injections was aware of what was being given. Injections were given into the deep subcutaneous tissues of the upper arm, a separate, dry-sterilised syringe being used for each subject. The first dose, which was given in early October, 1958, was of 0·1 ml.; the second dose a week later was 0·3 ml., the third dose, two weeks after the second, was 0·5 ml., a fourth, reinforcing dose, also 0·5 ml., was given in mid-January, 1959. On a personal record card, which was prepared for each man, were noted the dates of his injections and reactions to them. Two men who had originally been in the autogenous-vaccine group were given pool vaccine for the reinforcing dose because their bottles of vaccine had been damaged.

Reactions to Inoculation

Reactions were generally trivial. After each of the injections about a third of those receiving the autogenous or pool vaccines and a few of the controls had slight redness, swelling, and soreness at the injection site for 24–48 hours. In the autogenous vaccine group 2 men had more severe local reactions with an accompanying local lymphadenitis, 1 of them after both the second and the third injections and the other after the reinforcing dose only. In the pool vaccine group 1 man had a severe local reaction accompanied by mild general malaise following the reinforcing dose. There were a few mild general reactions after each of the injections in the pool and autogenous groups but none in the control group. 1 man in the autogenous-vaccine group experienced symptoms similar to allergic rhinitis starting 6–9 hours after each of the first three injections and clearing up in 48 hours; owing to release from the Service he did not have a reinforcing dose.

Recording Methods

Volunteers were urged at the beginning of the trial and reminded at intervals to report to their medical officer all respiratory infections however mild they might be. In this way, and because all flying personnel are well aware of the dangers of flying with a cold, it is believed that reasonably complete records were obtained. The assessment and the record of each illness were made by the station medical officers. As stated above, neither they nor the volunteers knew who had received the vaccines and who the saline control. The date of each illness reported and the diagnosis were noted on the back of the personal record card. To support this entry an illness record card was completed for each illness. On one side of this card were recorded certain features of the severity of the illness, including the number of days off full flying duties, a diagnosis, and an assessment of whether the illness was mild, average, or severe, taking into account both diagnosis and the patient's usual experience. The number of days off full flying duties included weekends, and where the man was on leave or off flying duties for any other reason the number of days that he would have been off duty was assessed. On the reverse side of the card were recorded the presence and severity of the following symptoms and signs within 48 hours of onset and after 48 hours: nasal discharge, sinus pain, postnasal drip, cough, sputum, and negative Valsalva sign. When a volunteer was absent from the station or omitted to report an illness when it occurred, a record card was completed as far as possible in retrospect. Uniformity in the compilation of records between the units taking part was ensured as far as possible by monthly visits to each of the stations.

Of the 320 original volunteers, 293 received all three initial injections and were followed for at least 1 month after the third dose. These were considered to be the minimum qualifications for inclusion in the final assessment of results. A further 17 volunteers left their stations at various times during the subsequent course of the trial, and another 8 men did not receive the reinforcing dose for various administrative reasons. Owing to these losses and also to some variation in the dates of injection the total period of follow-up tended to vary slightly with individuals, but it was found that the total numbers of weeks of exposure in each of the two vaccine groups and the control group were almost identical. Therefore the slight variations in the numbers and periods of follow-up were ignored.

TABLE I—INCIDENCE OF ALL RESPIRATORY ILLNESSES
(Attack-rates (%) in parentheses)

—	Autogenous vaccine	Pool vaccine	Control group
Total no. of volunteers	99	97	97
Total no. of illnesses	116 (*117%*)	119 (*123%*)	124 (*128%*)
Illnesses 3–6 weeks (incl.) after 3rd and reinforcing doses	34 (*34%*)	53 (*55%*)	52 (*54%*)
Illnesses during remainder of trial	82 (*83%*)	66 (*68%*)	72 (*74%*)
Illnesses 1–2 weeks after 3rd and reinforcing doses	43 (*43%*)	33 (*34%*)	28 (*29%*)
Illnesses during remainder of trial	73 (*74%*)	86 (*89%*)	96 (*99%*)

Results

The sickness records were analysed separately for the incidence and severity of all respiratory infections during the total period from the last of the three initial doses of vaccine to the end of the trial, and for two shorter periods within this time: (1) the period when the maximum effect of a normal immunological response would be expected, 3–6 weeks after inoculation, and (2) the period when the effects of any immediate but shortlived immunity would be expected, in the first 2 weeks after inoculation.

TABLE II—NUMBER AND PROPORTION OF ILLNESSES CLASSIFIED AS MILD

Illnesses	Autogenous vaccine	Pool vaccine	Control group
Total	51 (*44%*)	51 (*43%*)	50 (*40%*)
3–6 weeks (incl.) after 3rd and reinforcing doses	10 (*29%*)	24 (*45%*)	17 (*33%*)
During remainder of trial	41 (*50%*)	27 (*41%*)	33 (*46%*)
1–2 weeks after 3rd and reinforcing doses	21 (*49%*)	9 (*27%*)	12 (*43%*)
During remainder of trial	30 (*41%*)	42 (*49%*)	38 (*40%*)

Table I shows the sickness incidence for all respiratory illnesses during the periods defined above. The total illness-rates in the three groups were about the same, but during the period from the 3rd to the 6th weeks after inoculation those in the autogenous-vaccine group had significantly fewer illnesses than the controls

$$\left(\frac{\text{Difference}}{\text{Standard error}} = \frac{20}{7} = 2{\cdot}9\right)$$

On the other hand the sickness-rates in the autogenous-vaccine group were higher than in the controls during the remainder of the trial.

Table II shows the proportions of illnesses which were classified as mild. There was little difference in the severity of illnesses in the three groups shown by this method of assessment in each of the selected periods.

TABLE III—NUMBER AND PROPORTION OF ILLNESSES INVOLVING THE LOSS OF MORE THAN 3 DAYS' FLYING-TIME

Illnesses	Autogenous vaccine	Pool vaccine	Control group
Total	54 (*47%*)	64 (*54%*)	68 (*55%*)
3–6 weeks (incl.) after 3rd and reinforcing doses	18 (*53%*)	24 (*45%*)	28 (*54%*)
During remainder of trial	36 (*44%*)	40 (*61%*)	40 (*56%*)
1–2 weeks after 3rd and reinforcing doses	14 (*33%*)	20 (*61%*)	15 (*54%*)
During remainder of trial	40 (*55%*)	44 (*51%*)	53 (*55%*)

TABLE IV—NUMBER AND PROPORTION OF ILLNESSES IN WHICH PURULENT SYMPTOMS OR SIGNS PERSISTED MORE THAN 48 HOURS FROM ONSET

Illnesses	Autogenous vaccine	Pool vaccine	Control group
Total	51 (*47%*)	66 (*55%*)	68 (*55%*)
3–6 weeks (incl) after 3rd and reinforcing doses	13 (*38%*)	27 (*51%*)	26 (*50%*)
During remainder of trial	41 (*50%*)	39 (*59%*)	42 (*58%*)
1–2 weeks after 3rd and reinforcing doses	19 (*44%*)	16 (*48%*)	19 (*68%*)
During remainder of trial	35 (*48%*)	50 (*58%*)	49 (*51%*)

It was particularly relevant to this study to know whether the volunteers who were vaccinated lost less flying-time than the controls Table III shows that they did not, except to a small degree during the first 2 weeks after inoculation with autogenous vaccine

If the vaccine were effective in shortening the stage of secondary infection of colds, fewer of the vaccinated persons would be expected to show purulent symptoms lasting more than 48 hours from onset than the controls In fact, as is shown in table IV, this was so for those receiving the autogenous vaccine, mainly in the period immediately following inoculation but also to some extent in the period 3–6 weeks after inoculation, although in neither instance was the reduction very great

Illnesses diagnosed as common cold formed 86% of the total and were almost equally distributed among the two vaccine groups and the controls All results were substantially the same when these illnesses were considered separately

Comment

It is clear from these results that autogenous bacterial vaccines as administered by us are unlikely to have any practical application in dealing with the problem of the common cold among flying personnel of the Royal Air Force There was, however, an interesting reduction in the incidence of illness in the autogenous-vaccine group in the period when it might be expected, between the 3rd and 6th weeks after inoculation Although there is little supporting evidence of reduced severity or duration of those colds which were reported during this period, there was some reduction in the number in which purulent symptoms persisted These observations are difficult to explain, since a vaccine designed to prevent secondary bacterial infection would be expected to reduce the severity of illnesses rather than their incidence Possibly, however, the reduction in severity of some colds was such that it led to under-reporting of these mild incidents Our results thus stand in contrast to those of Ritchie, but our volunteers received only four injections, whereas his were given them weekly for at least 8 weeks and many for the whole winter It is also possible that flying personnel of the R A F, who are carefully selected on medical grounds, suffer less from the bacterial complications of the common cold than factory volunteers, a proportion of whom were subject to heavy colds Autogenous bacterial vaccines, perhaps in greater dosage, may therefore merit further investigation among less healthy persons

Summary

A controlled trial of autogenous bacterial vaccines for the common cold among 293 flying personnel of the Royal Air Force is reported Three groups were formed and given autogenous vaccine, a pool vaccine, or phenol saline in a course of three initial doses in October, 1958, and a reinforcing dose in January, 1959 The volunteers were observed until the end of March, 1959, and records were made of all their respiratory infections during this time

The total incidence and severity of respiratory illnesses in the three groups were very similar, and such vaccines are, therefore, unlikely to have any practical application to the problem of the common cold among flying personnel of the Royal Air Force There was, however, a statistically significant reduction in the illness attack-rate in the autogenous-vaccine group during a limited period of 3 to 6 weeks after the third and reinforcing doses

Our thanks are due to the medical officers at R A F College, Cranwell, and at R A F Stations Oakington and Thorney Island for their valuable cooperation and assistance with every stage of this investigation, and to the Director-General of the Royal Air Force Medical Services for permission to publish the results

DYSPEPSIA DUE TO INHALATION OF CARBON TETRACHLORIDE VAPOUR

G KAZANTZIS
M B, Ph D Lond, F R C S
OF THE DEPARTMENT FOR RESEARCH IN INDUSTRIAL MEDICINE (MEDICAL RESEARCH COUNCIL), LONDON HOSPITAL, E 1

R R BOMFORD
D M Oxon, F R C P
PHYSICIAN, POPLAR HOSPITAL, LONDON, E 14

PATIENTS often blame their work for their indigestion, though this symptom is rarely directly attributable to occupation Any common symptom may, however, arise from work and the connection may be missed unless one asks in detail what are the actual processes involved Even then the patient may be unaware of the toxic nature of the materials that he uses, and the poison responsible may play a minor role in the main process on which he is engaged

A man of 34 years of age attended Poplar Hospital complaining of anorexia, nausea, and occasional vomiting with a feeling of abdominal discomfort not amounting to pain He had had these symptoms intermittently for two years, and on this occasion for about two months, during which time he felt unusually depressed and irritable No abnormal signs were found on clinical examination

One odd feature in the history—that the dyspepsia was better at weekends and built up during the week—led to more detailed inquiry about the patient's work It was then found that he was exposed to the vapour of carbon tetrachloride, and that other workers had developed similar symptoms in the past few months and some had consulted their doctors A visit to the factory was arranged

Description of the Factory

There were 18 people—14 men and 4 women—employed in a workshop with an area of about 3000 sq ft, divided into two parts by a wooden partition which did not reach the roof The windows were kept closed, and there was no mechanical ventilation The room was heated by indirect gas convector heaters, each of which was connected to a flue passing through the roof On entering the room one could detect no atmospheric contaminant, but one could smell carbon tetrachloride in the immediate environment where it was used

Process

The factory processes raw quartz in the manufacture of crystals for electronic equipment The quartz is examined for flaws, before being orientated and cut with diamond-impregnated saws After X-raying and further cutting, the crystal blanks are stuck by means of a resinous wax on to lapping plates and ground on carborundum. The crystals are cleaned in carbon tetrachloride to remove the resinous wax, etched with hydrofluoric acid, then further cleaned by being passed through solutions of chromic acid, distilled water, methylated spirit, and acetone, and finally dried in an oven The crystals are adjusted to their correct frequency by the addition of gold, effected by electroplating in a gold-cyanide solution Finally, the crystals are mounted and cleaned by being passed through the series of solvents again, starting with carbon tetrachloride. To facilitate the cleaning process, an ultrasonic vibration of about 40,000 cycles per second is passed through the carbon tetrachloride solution. About two Winchester quarts (five litres) of carbon tetrachloride are used weekly, although much of this is thrown away

When a beaker of carbon tetrachloride was placed in the ultrasonic cleaning apparatus, drops of carbon tetrachloride could be seen spraying out from the beaker, and the characteristic odour of its vapour was obvious Carbon tetrachloride could also be smelt in the vicinity of another bench, where the plates were cleaned with cloth dipped in the solvent.

Clinical Survey

Medical and occupational histories were taken from 17 of the 18 employees, and 16 of the 17 workers interviewed were examined clinically

Of the 17 workers seen, 15 complained of symptoms, which are shown in table I The pattern was similar in all Nausea was usually first noticed on a Tuesday or a Wednesday afternoon and increased in severity as the week progressed Anorexia was most severe for the evening meal These symptoms were accompanied in most cases by upper abdominal discomfort, which did not amount to pain, but was described as an unpleasant distended feeling The incidence of vomiting was more varied In the more severe cases vomiting occurred up to four times in the day, usually on a Thursday or a Friday, and took place both at work and at home in the evenings

Of the remaining symptoms, depression was the most pronounced, and this was noticed by workers who had never had such feelings before Complaints were made of irritability and of unusual shortness of temper with children at home There were no complaints of lassitude or somnolence In all but 2 of the workers the symptoms had first manifested themselves during the preceding four months, since the autumn of 1958, and were most severe in the weeks prior to our visit This coincided with the closure of windows in the colder weather

The clinical examinations were performed five days after precautions had been taken to reduce further exposure No abnormal physical signs were discovered The fundi and visual fields were normal 3 men had mild upper abdominal tenderness, but without guarding No abnormalities were found in the urine Case 7 (table I) when originally examined in hospital had a raised serum-glutamic-oxalate-transaminase (76 units per ml.), but this test was normal in this man and in 7 others at the time of the clinical examinations

TABLE II—ATMOSPHERIC CONCENTRATION OF CARBON TETRACHLORIDE IN DIFFERENT SITES IN THE WORKSHOP AFTER RUNNING THE ULTRASONIC EQUIPMENT FOR THREE HOURS (*a*) BEFORE COVERING BEAKERS CONTAINING CARBON TETRACHLORIDE, (*b*) AFTER COVERING THE BEAKERS

Site	Concentration of carbon tetrachloride			
	Before covering beakers		After covering beakers	
	Parts per million	mg per c.m	Parts per million	mg per c.m.
Adjacent to ultrasonic apparatus				
Bench 1	97	620	8	50
Bench 2	70	450	9	60
Bench 3	67	430	0	0
On other side of partition				
Bench 4	45	290	<8	<50
Bench 5	47	300	<8	<50
Bench 6	45	290	<8	<50

Environmental Survey

The concentration of carbon tetrachloride in the atmosphere at different sites in the workshop was estimated after the ultrasonic equipment had been running continuously for three hours, and repeated after the control measures suggested were put into practice The atmospheric samples were taken into two impingers in series with a handpump, carbon tetrachloride in the samples being estimated by the technique described by Strafford et al (1956) The results obtained at various sites in the workshop are given in table II A maximum allowable concentration in the atmosphere of carbon tetrachloride of 25 parts per million (160 mg per c m) was recommended by the American Conference of Governmental Hygienists (1959) The concentrations obtained under the original conditions were considerably in excess of this recommended figure, as can be seen in table II, which also shows the effectiveness of the simple control measures instituted The beakers containing carbon tetrachloride were covered, and the cleaning of plates with cloth dipped in carbon tetrachloride was stopped All the workers were symptom-free within one week, and there were no recurrences up to six months later

Discussion

That exposure to high concentrations of carbon tetrachloride produces narcosis, liver damage, and kidney damage is well known It is less well known, however, that exposure to lower concentrations may be responsible for less serious effects In a detailed investigation of workers subject to prolonged exposure to carbon tetrachloride, Stewart and Witts (1944) found a high incidence of gastrointestinal upset and mental hebetude The symptoms were similar to those in our patients with the difference that diarrhœa was prominent in their group Their radiological investigations showed hypermotility with accompanying irritability and irregular contraction throughout the alimentary tract, and they suggested that these effects were produced by autonomic

TABLE I—SYMPTOMS PRESENT IN 17 WORKERS EXPOSED TO CARBON TETRACHLORIDE

Anorexia	−	+	+	+	+	+	+	+	−	+	+	+	−	−	+	+	−
Vomiting	−	−	−	+	+	+	+	+	−	−	−	+	−	−	+	−	−
Flatulence	+	+	−	−	+	+	−	−	−	+	−	+	−	−	+	−	−
Epigastric discomfort or distension	+	+	+	+	−	+	+	−	−	+	+	−	−	+	+	−	−
Depressive symptoms, headache, giddiness	+	+	+	+	+	−	+	−	−	+	−	+	−	+	+	−	−
Duration of symptoms (mos)	4	4	2–3	2	2	24	24	2–3	0	$^1/_2$	$2^1/_2$	2	$^1/_4$	2–3	$1^1/_2$	$2^1/_2$	0

stimulation They found no evidence of liver damage on liver-function tests, and they disputed the view of Elkins (1942) that such symptoms reflected an early stage of liver damage

Stewart and Witts were unable to measure atmospheric concentrations of carbon tetrachloride Smyth and Smyth (1936), on the basis of animal experiments and clinical studies, concluded that 100 parts per million of carbon tetrachloride in the atmosphere would be a reasonable maximum allowable concentration This figure has steadily fallen over the years to the present American level of 25 parts per million The findings presented here show that a concentration of carbon tetrachloride in the working environment of the order of 45–100 parts per million can be associated with the appearance of symptoms of poisoning

Summary

A group of factory workers developed nausea, and other symptoms increasing in severity in the latter half of each working week. These symptoms were attributed to exposure to the vapour of carbon tetrachloride in a concentration of approximately 45–100 parts per million

We wish to thank Dr Donald Hunter and Dr A I G McLaughlin for their advice, and Mr E King, Mr P N Casbolt, and Mr D E Fine, of the Department for Research in Industrial Medicine, Medical Research Council, for carrying out the atmospheric sampling and analyses

POLYNEURITIS AND CENTRAL HYPERTENSION DUE TO NON-PAROTITIC MUMPS

Ian H. Porter
M B Lond
LATE HOUSE-PHYSICIAN

Christopher Pallis
D M Oxon, M R C P
LECTURER IN NEUROLOGY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

From the Department of Medicine (Neurology), Postgraduate Medical School of London, W 12

The nervous system is not infrequently involved in infections with the mumps virus A short, benign, lymphocytic meningitis is the commonest neurological complication of the disease and has been reported in as many as a third of infected patients (Holden et al 1946, Brown et al 1948) It may cause no symptoms and be detected only by routine examination of the cerebrospinal fluid

Involvement of the nervous system usually follows the development of clinically obvious parotitis within a period of a week Occasionally the parotitis may be delayed

Eberlein and Lynxwiler (1947) showed, in a review of 280 cases of mumps " meningoencephalitis " reported since 1918, that in about 10% of cases the neurological illness antedated the parotitis by several days In a further 13% of cases clinically evident parotitis did not occur at any stage of the illness In most instances the diagnosis was based on the occurrence of the characteristic neurological illness during epidemics of mumps, or in close contacts of known cases of parotitis In the more recent cases the diagnosis was based on the development, in patients with meningoencephalitis, of diagnostic changes in mumps antibody titre (Kane and Enders 1945) The occurrence of meningoencephalitis due to serologically proven mumps, without parotitis, is now well documented (Enders 1946, Kilham et al 1949, Kilham 1949, Adair et al 1953, Horstmann 1956, Overman 1959)

Involvement of the nervous system may on occasion show itself in the course of mumps by conditions other than meningitis Facial palsy, labyrinthitis, nerve deafness, and other localised forms of neuritis are well-known complications Encephalitis and myelitis, clinically and pathologically very similar to the parainfectious encephalomyelitis due to measles, rubella, and varicella (Miller et al 1956) may occur

Polyradiculitis and polyneuritis are extremely rare complications of mumps Miller et al (1956) could find only 9 cases reported between 1934 and 1956 Parotitis was present in every case, although in 3 instances it developed only after the onset of neurological symptoms

No cases appear to have been described hitherto of nonparotitic mumps presenting as polyneuritis We here report such a case, which had two further most unusual features—namely, severe and fairly long-continued hypertension of " central " origin and the onset of meningoencephalitic symptoms well after the development of frank polyneuritis Although " central " hypertension is a well-known feature of certain cases of bulbar poliomyelitis and has been reported in " acute infective polyneuritis " (Woltman and Kernohan 1955) it does not appear to have been previously described in " allergic " parainfectious polyneuritis or polyradiculitis

Case-report

Mrs A, aged 17, was admitted to Queen Charlotte's Hospital in the 32nd week of her first pregnancy and treated with streptomycin on account of a urinary infection Throughout this pregnancy her blood-pressure never rose above 130/80 mm Hg On Dec 30, 1958, she gave birth, at term and by normal delivery, to a 6$^1/_4$ lb boy. On the second day of the puerperium mild pyrexia developed, and this persisted for two weeks On the eighth day she complained of " pins and needles " in her hands and feet and of an unsteady gait She was found to have absent reflexes in the lower limbs and slight sensory impairment in both feet

Apart from rheumatic fever in childhood she had always been healthy There was no personal or family history of epilepsy There had been no recent contact with any case of mumps

Investigations

The patient had mild normocytic anæmia (Hb 75%) and total white blood-cells 12,500 per c cm The Paul-Bunnell test was negative and blood-cultures were sterile The urine contained a trace of albumin and yielded a scanty growth of coagulase-negative *Staphylococcus albus* The blood-urea was 23 mg per 100 ml. The cerebrospinal fluid (C S F) was under normal pressure but contained 140 mg of protein per 100 ml, the cell count and sugar content were normal and the fluid was sterile on culture

On the basis of the clinical findings and of the albuminocytological dissociation in the C S F, Guillain-Barré syndrome was diagnosed

Course

On the thirteenth day of the puerperium the patient had nine very severe generalised convulsions within a period of fourteen hours, and she remained unconscious for forty-eight hours For the first time her blood-pressure was found to be raised (180/130 mm Hg) White blood-cells had now increased to 18,000 per c mm The serum-electrolytes were normal and the urine contained 13 mg of protein per 100 ml and grew a β-hæmolytic streptococcus on culture A further lumbar puncture yielded C S F containing 150 mg of protein per 100 ml, but only 1 lymphocyte per c mm

The fits were treated with paraldehyde and chlorpromazine, and the patient was subsequently given sodium phenytoin (50 mg b d) Lactation was suppressed by three injections of 15 mg of stilbœstrol, given on successive days, and the urinary infection was treated with a five-day course of chloramphenicol Her blood-pressure remained persistently raised at 180/130 mm Hg, and treatment with reserpine (0 25 mg b d.) was started.

During the following week her level of consciousness improved, but severe paralysis of the limbs developed. In view of this, the associated convulsions, and the persistently raised blood-pressure, she was transferred to Hammersmith Hospital on Jan 19, 1959

Condition on Transfer

On admission the patient complained of severe occipital headache, double vision on looking to the left, circumoral parasthesiæ, and slight difficulty with speech and swallowing She was unable to move her limbs and could not turn about in bed. There were no paræsthesiæ in the limbs Sphincter control was not impaired. Temperature 98°F, no rash, lymphadenopathy, enlargement or tenderness of the salivary glands, or sternal tenderness, body-weight 84 lb Pulse-rate 120 per minute, blood-pressure 200/120 mm. Hg

The patient was apathetic and had mild meningism. The fundi were normal. She had bilateral external rectus pareses, coarse nystagmus on looking to the right and fine nystagmus on looking to the left, and some rotatory nystagmus on upward gaze, bilateral facial paresis, and mild bilateral palatal and pharyngeal palsies There was severe generalised symmetrical wasting of the upper and lower limbs with much associated weakness, especially distally, and moderate weakness of the trunk muscles

The muscles were tender and there were early contractures at the right elbow and ankle All the tendon reflexes were absent. The plantar responses were feebly flexor There was impairment of light touch and pain sense, and loss of vibration and postural sense in the hands, forearms, feet, and legs of "glove-and-stocking" distribution.

Further Investigations

The blood picture was normal. The erythrocyte-sedimentation rate was 25 mm in the first hour (Westergren) The Paul-Bunnell test was again negative. Serum-electrolytes, blood-urea, and liver function tests were normal The urine contained no albumin, porphyrins, or other abnormal constituents and was sterile on culture. The Mantoux test was negative at 1 10,000 The C.S F contained 490 mg of protein per 100 ml. but was otherwise normal An intravenous pyelogram was normal

An electroencephalogram (E.E G) on admission showed a severe generalised abnormality with no normal rhythms present. It was dominated by very large bilaterally synchronous slow waves, most prominent precentrally and occasionally of higher amplitude on the right side

As no obvious factors had been discovered to account for the polyneuritis and subsequent meningoencephalitis, serum was sent to the Central Public Health Laboratory, Colindale At no stage were abnormal titres of antibodies against any of the known "respiratory" viruses found, but the following results were unexpectedly obtained

Date (1959)	*Day of disease*	*Mumps "virus particle antigen*	*Mumps soluble' antigen*
Jan. 13	6	1/32	1/16
, 23	16	1/64	1/32
Feb 19	43	1/8	1/8
March 13	65	1/8	1/8

These findings were interpreted by Dr C E D Taylor, of the routine diagnostic laboratory, Colindale, as strongly suggestive of recent infection with mumps virus The serum-amylase was normal

Progress

The patient was given phenobarbitone (50 mg t.d.s) and sodium phenytoin (100 mg t.d.s), this was gradually reduced *pari passu* with the improvement in the E.E.G findings and was finally stopped when these findings had returned to normal She received regular physiotherapy

Two days after admission to Hammersmith Hospital she had two further generalised convulsions, each lasting about two minutes, in which the only lateralising features were deviation of the head and eyes to the right. During the second attack her blood-pressure rose to 220/140 mm Hg

The patient made steady and fairly rapid progress Four weeks after the start of her illness the bulbar signs had disappeared, and by the fifth week the external ocular movements were normal and she had no nystagmus or circumoral parasthesiæ, she could sit up and turn about in bed unaided By the ninth week she could walk with assistance, and by the eleventh the sensory signs had cleared The hypertension gradually subsided during convalescence, the blood-pressure eventually settling at 120/80 mm. Hg The E E G also reverted to normal Three months after the onset of her illness the patient could walk unaided and normal menstruation had returned.

The only residual disability is moderate weakness of both anterior tibial muscles, causing partial bilateral foot-drop Improvement is continuing

Comment

Clinically this case resembled previously reported cases of mumps polyneuritis (Miller et al 1956) in the severity of the tetraplegia, its association with lower-cranial-nerve palsies, and the considerable albuminocytological dissociation of the C S F The present case differed from the hitherto reported cases in the severity of sensory loss (rather an inconstant feature in previous cases and, when present, rarely extreme) and in the development of meningoencephalitis (nuchal rigidity, fits, and stupor), *subsequent to* the development of polyneuritis Of the various parainfectious neurological syndromes, polyneuritis has the longest latent period It is hardly ever followed by meningoencephalitis

The hypertension was assumed to be of "central" origin in view of its acute onset and eventual complete subsidence, the absence of any alternative cause, and the known association of hypertension with certain inflammatory disorders involving the brain-stem

The diagnosis of mumps in non-parotitic cases must of necessity rest on laboratory evidence Isolation of the virus from the C S.F has proved feasible in a large proportion of cases of lymphocytic meningitis due to mumps (Kilham 1949, Kilham et al. 1949), but in patients presenting with other neurological disorders serological evidence has to be relied on In our patient the serum showed increases of complement-fixing-antibody titre equal to or exceeding the fourfold increase suggested by Kilham (1949), and subsequently accepted by others (Feller and Jordan 1950, Adair et al 1953, Horstmann 1956, Wolman 1957), as diagnostic

We wish to thank Mr T L T Lewis, who referred the patient to us, and Dr C E. D Taylor, for his help with the serological investigations

TREATMENT OF UNUSUAL CASE OF ANURIA

IRIS I J M GIBSON[*]
M A , M B Glasg , F R F P S , D Obst
LATELY SENIOR HOUSE OFFICER, MEDICAL RESEARCH COUNCIL
CLINICAL CHEMOTHERAPEUTIC RESEARCH UNIT,
WESTERN INFIRMARY, GLASGOW

THIS case of acute renal failure, treated by the conservative method of Borst (1948) and Bull et al (1949), presented unexpected and interesting features

Case-record

An unmarried woman, aged 48, had a rigor, followed by dysuria, frequency, and nocturia, ten days before admission on Oct 29, 1958 Nausea and retching began four days later She had occasionally had frequency and dysuria, for one to two days, throughout several years Since 1952 she had been incapacitated by rheumatoid arthritis, and, because of this, had taken 200 mg phenylbutazone daily for five weeks prior to admission She was in hospital in 1952, because of the arthritis, and in 1955, suffering from " pneumonia "

She had typical rheumatoid deformities Her temperature was 100 6°F There was no other abnormality on clinical examination, and her tongue was moist The urine contained many pus cells and fine granular casts, and culture showed *Escherichia coli* Albuminuria ($^3/_4$ part Esbach) and ketonuria were found, and the reaction to Benedict's solution was green The hæmoglobin level was 12 g per 100 ml , white blood-cells 10,600 per c mm , erythrocyte-sedimentation rate 96 mm in the first hour (Westergren), blood-urea 41 mg per 100 ml , serum-proteins normal The lupus-erythematosus-cell test, Wasserman reaction, and gonococcal fixation test were negative, and the Rose-Waaler test was strongly positive The fasting blood-sugar was 93 mg per 100 ml X-ray of chest and electrocardiogram were normal

Treatment and Course

Acute pyelonephritis was diagnosed, and treatment started with alkalis, fluids, light diet, and 'Sulphatriad' 1 g t i d Intake and output were satisfactory, though the patient vomited small quantities of fluid. On the fourth day she complained of central abdominal colic, but no abnormality was detected. Urinary output on the sixth day was only 235 ml Sulphatriad was discontinued, and four pints of 5% glucose given intravenously without effect. The patient was anuric for eleven days She was placed on the regime outlined by Bull (1958) An intragastric drip was maintained for twenty-two days, during which 250–300 g glucose was given daily Vomiting was persistent, but the fluid lost was easily replaced Water and electrolytes lost through diarrhœa were replaced by equivalent fluids Antibiotics and vitamins were given orally The grave illness ran a typical course, with the highest blood-urea level—310 mg per 100 ml —on the eighteenth day The serum-potassium level was high at first, but with the high carbohydrate intake, and two injections of isobutyrate crystals of testosterone ('Perandren' 50 mg), it remained just within normal limits until diuresis began, when it fell to dangerously low levels which proved difficult to correct with intensive oral potassium

On the fourth day of anuria cystoscopy was performed The bladder was healthy, and the ureteric orifices were normal The ureteric catheter was held up at 1 cm on the left side Pyelogram of the right kidney was normal The few drops of urine in the bladder contained many pus cells, a very occasional red blood-cell, and, on culture scanty proteus and enterococci. No crystals were seen Serum-sulphonamide was 4 2 mg per 100 ml

Two days later the patient was very ill, and rapidly became dehydrated and confused Her condition resembled that of a diabetic almost in coma. Blood-sugar at 3 P M was 760 mg per 100 ml Despite 24 units of soluble insulin, and oral saline (one-third physiological), it was 900 mg by 10 30 P M 60 units of soluble insulin brought the level down gradually to 100 mg at 9 A M Throughout the night the patient was paranoid, with Kussmaul respirations and rhonchi at the lung bases The danger of hyperglycæmia was now appreciated, and blood-sugar levels were controlled by insulin (see figure) With this, and control of infection, the patient slowly recovered She developed a generalised drug rash after intramuscular tetracycline, and again after intramuscular penicillin

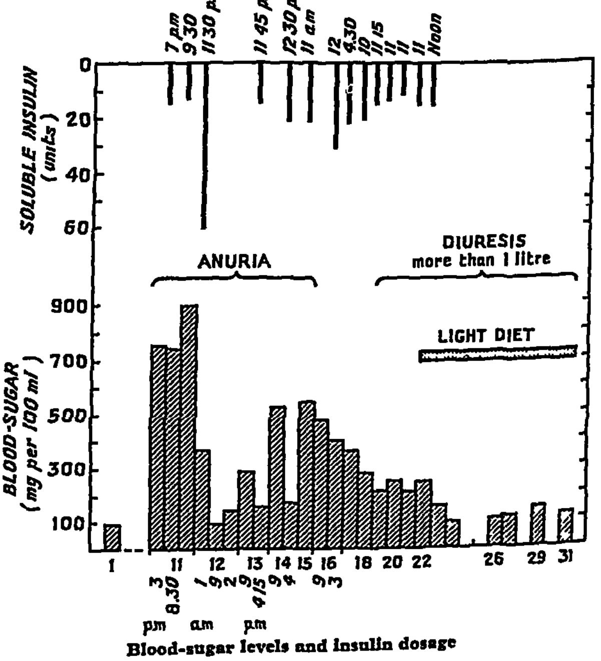
The first urine passed after eleven days, and blood taken at the same time gave blank values for phenylbutazone This was eighteen days after the last dose

On the thirtieth day of illness liver-function tests were found to be abnormal thymol flocculation+++, cephalin-cholesterol++++, prothrombin-time 27 sec., serum-albumin 3 2 g, globulin 3 2 g, per 100 ml These slowly became normal. Two oral, and one intravenous, glucose-tolerance tests gave diabetic curves, and also suggested abnormal leakage of glucose in the urine Urea-clearance was 29%, and maximum concentration of urine 1006 Seven months later an oral glucose-tolerance test was normal, concentration reached 1012, and urea-clearance was 45%

The case-notes for 1955 showed the the patient's previous illness had been acute pyelonephritis, with *Esch coli* infection, following phenylbutazone for several weeks Treatment was with sulphatriad and alkalis, but, because of vomiting, finally with tetracycline The urinary output was low on two occasions (7 oz , 14 oz) at times when intake was low

Discussion

This patient's history emphasises two points in the conservative treatment of acute renal failure (1) blood-sugar estimations are essential, and (2) insulin control of hyperglycæmia will probably be necessary Insulin is generally administered, primarily in order to promote the formation of glycogen and a potassium-glycogen cellular complex, to prevent a dangerously high serum-potassium level (Fenn 1940, Bywaters and Joekes 1948, Bull et al 1953) De Wardener (1958) refers to this, but not to the necessity for insulin control to prevent hyperglycæmia In the present case it was not appreciated that with a satisfactory potassium level hyperglycæmia would be so severe and would cause such physical and mental deterioration Tests suggested that carbohydrate control was probably disturbed, but at first it was known only that the patient



Blood-sugar levels and insulin dosage

---

[*] Present address The Royal Infirmary, Glasgow

had a normal fasting blood-sugar Evans et al (1953) have pointed out the importance of routine blood-sugar estimations, since high levels develop in many cases Rennie (1958) recommends that the blood-sugar be estimated every third day, and that 10 units of soluble insulin be given three times each day if the level much exceeds 250 mg per 100 ml.

The cause of acute renal failure in this patient has not been accurately determined. She had an acute urinary infection and probably chronic renal infection, on admission On ureteric catheterisation, however, there was no abnormality and no crystals were found This suggested that the sulphonamide was not responsible, and the blood-sulphonamide level was low Tests suggested hepatocellular damage, and an upset of carbohydrate metabolism, which, in association with abdominal pain, might have been due to pancreatitis or hepatitis The patient had received 200 mg phenylbutazone daily for five weeks, and had had a remarkably similar illness in 1955 following the same drug Twice while in hospital she exhibited hypersensitivity to drugs Her latest illness was probably due to idiosyncrasy to this drug associated with already poor renal function. During convalescence she appeared to have diminution in function of the proximal convoluted tubule, shown by daily glycosuria. This is a rare sequel to acute renal failure (Bull et al 1950), but could be a nephrotoxic effect.

Toxicity of phenylbutazone can develop after small doses (Steel and Moffatt 1954, Wood 1954, Fraser 1955) In the case reported by Johnson and Larkin (1954) the patient had contracted kidneys and poor renal function, which they suggested should preclude the use of the drug Toxic effects may occur after the drug has been stopped Blood-levels fall over seven to fourteen days, and blank values are found after fourteen days (Bruck et al 1954, Huffman et al. 1954, Wood 1954) Phenylbutazone has been reported as causing widespread visceral damage, including hepatitis, pancreatitis, and renal tubular damage and has caused acute renal failure (Bourne 1953, Freeland et al. 1953, Stifel and Bunheimer 1953, Bruck et al 1954, Engleman et al 1954, O'Brien and Storey 1954, Fraser 1955, MacCarthy and Jackson 1955) The most interesting parallel is with the case reported by Nassim and Pilkington in 1954, where the urine contained albumin, bile, urobilinogen, and granular casts a few days after phenylbutazone was discontinued

Ten days later there was pronounced glycosuria and a diabetic glucose-tolerance curve, and the patient required insulin for ten days Serum-amylase was normal, but liver-function tests were abnormal, and liver biopsy showed changes thought to be due to toxic damage. It was several months before liver-function tests and glucose-tolerance became completely normal. No previous case had shown transient hyperglycæmia responding to insulin. The involvement of so many viscera was thought to suggest a hypersensitivity reaction.

Summary

A case of acute renal failure, treated by conservative methods, is described.

Blood-sugar estimation is important in such cases, and hyperglycæmia must be controlled by insulin.

In the present case the cause was apparently hypersensitivity to phenylbutazone.

I thank all those in the unit and the Western Infirmary who worked so hard for this patient, and in particular Dr James Reid for his advice and encouragement

FIBROCYSTIC DISEASE OF THE PANCREAS IN A MAN AGED 46

BRIAN L MARKS
M.D Melb, M R.C.P, M.R A C.P
PHYSICIAN TO OUTPATIENTS, ROYAL MELBOURNE HOSPITAL

CHARLOTTE M ANDERSON
M.D, M Sc Melb
DEPUTY DIRECTOR, CLINICAL RESEARCH UNIT,
ROYAL CHILDREN'S HOSPITAL, MELBOURNE

IN recent years patients with fibrocystic disease of the pancreas have been observed to reach greater age in a better clinical state than previously Most of this improvement has been attributed to the use of antibiotics and other measures in controlling the pulmonary infection which so frequently causes death But an increasing number of cases has been diagnosed in later childhood, and there have been predictions that cases would be discovered in adult life, especially where the full established clinical picture had not been present from birth (Andersen 1958) Andersen (1958) mentions a patient aged 35 years who was found at necropsy to have certain features suggestive of this condition, but she said that the diagnosis was far from established in that instance

In the case described here a man aged 46 years presented with a combination of chronic pulmonary suppuration and pancreatic insufficiency, and he is thought to have fibrocystic disease of the pancreas

Case-record

A shopkeeper, aged 44, was referred to one of us (B L. M.) in April, 1958, with a history of cough and sputum for as long as he could remember, and certainly since the age of 2½ years His sputum, which had always been yellow, had in recent years increased in amount to 2 oz. daily He recollected wheezing in childhood, but this was abolished by coughing up his sputum. Each morning he spent a few minutes "clearing" his chest. Effort tolerance had been somewhat impaired for years, although he could still climb three flights of stairs quite briskly There were days when he was more wheezy than usual, but the dyspnœa was constant. Purulent nasal discharge had been present since childhood. His nose was usually blocked and his sense of smell was poor Colds were common. He had had pneumonia at the ages of 2½, 7, 10, 29, and 34 years, and had been severely ill on the last two occasions

His mother did not consider him to be strong as a child, and he had always looked after himself carefully His sisters were of normal height, but he was usually the shortest in his class His appetite was always large, but for some years it had been voracious He passed two motions daily during childhood, and

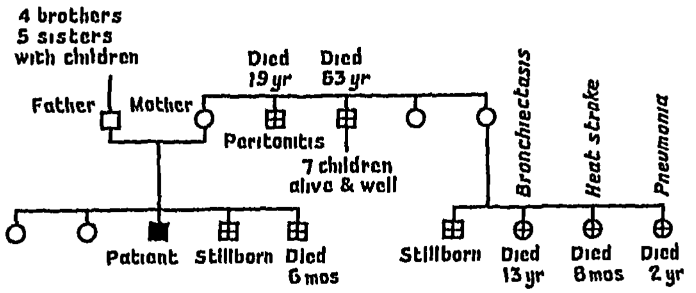

Fig 1—Family tree, showing evidence of deaths in childhood

had noted fatty oozing from the anus since the age of 20 Severe diarrhœa started after his attack of pneumonia at the age of 29, and has continued since, there have been five to eight motions daily, orange and often fluid

Vision had been poor for two years and had been improved by local injections of cortisone He had been married for many years but had had no children Sterility had been investigated seventeen years previously, his wife was then said to be normal He was stated to have had azoospermia Testicular biopsy was normal

Family History

The family history (fig. 1) was of some interest One brother was stillborn and the other died at the age of 6 months, for some time before death this child had opisthotonus, the cause of which was not ascertained Two sisters were alive and well One of his mother's sisters had borne 9 children, 5 of whom were alive and well, but of the remainder 1 had been stillborn, and 3 daughters had died early in life 1 of these had proven bronchiectasis and was known to have been puny, she died unexpectedly at the age of 13 years during a general anæsthetic Another child died at the age of 8 months, probably of heat stroke. The 3rd child died at the age of 2 years of pneumonia, but no further information is available about her

Physical Examination

The patient was short, slight, and wheezy Bilateral submandibular salivary-gland enlargement was apparent There was no finger-clubbing The anteroposterior diameter of the chest was increased, movement was poor, and cardiac and hepatic dullness were diminished, the percussion note was generally hyperresonant, many rhonchi were audible, and there were fine crepitations posteriorly up to the level of the scapular angles, air entry was quite good Examination of the ocular fundi showed bilateral choroiditis with vitreous opacities The liver and spleen were not palpable

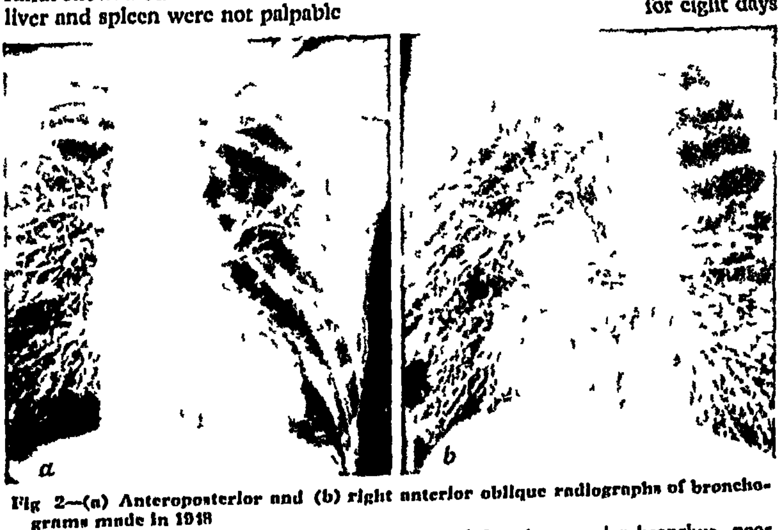

Fig 2—(a) Anteroposterior and (b) right anterior oblique radiographs of bronchograms made in 1948

These show "bangling" and dilatation in the left apicoposterior bronchus, poor filling and irregularity of calibre in many of the branches of the left lower lobe, and dilatation and irregularity of branches of the right middle lobe and right posterior basal segment

Investigations

X-ray examination of the chest showed generalised fine fibrosis, more pronounced in the lower zones Bronchography had been carried out in 1948 (fig 2) Widely distributed "bronchitic" change was apparent comprising sparse branching, irregularity of bronchial calibre, and "bangling", but, although present in most lobes, it was not gross. Several small bronchi were dilated, and here peripheral puddles of contrast medium were visible suggesting slight bronchiectasis Respiratory function tests showed the typical pattern of a moderately severe obstructive defect The tests were considered compatible with chronic bronchitis with or without emphysema The ventilatory response to exercise was rather high The ventilatory tests conformed to the pattern found in children with fibrocystic disease of the pancreas with moderate pulmonary involvement (Gandevia and Anderson 1960) Sputum culture did not reveal any pathogens

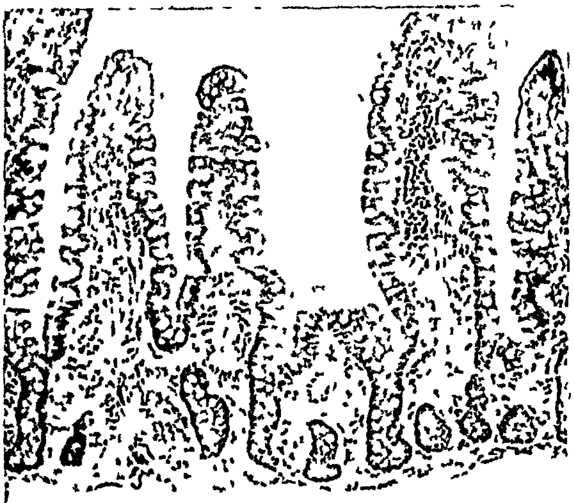

Fig 3—Section of the jejunal biopsy specimen (×150)

This shows relatively normal villous form, with some infiltration by plasma cells and lymphocytes Goblet cells are numerous and swollen and granular eosinophilic-staining mucous material is present in the crypts

The stools were bulky and greasy and contained oil droplets In fat-balance studies the patient had a daily fat intake of 190 g for eight days, and during the second four days of this period fat output in the stools averaged 140 g daily Duodenal intubation yielded clear viscid orange fluid of pH 7 0–8 6 Three specimens contained no trypsin, amylase, or lipase Aspirate was again obtained after giving 1 unit of secretin per kg body-weight by intravenous injection In the forty minutes preceding the injection 14 0 ml of fluid was obtained containing 0 22 millimol of bicarbonate (normally 90–199 ml containing 10 7–17 75 millimols) In the forty minutes *following* secretin the output rose to only 26 5 ml containing 1 03 millimols of bicarbonate The pH of two specimens obtained before secretin was 7 5 and 7 8, these contained 0 8 and 0 5 unit of lipase respectively, but neither trypsin nor amylase After secretin the specimens were of pH 8 0 and 8 2, they contained 0 8 and 0 7 unit of lipase, but again neither trypsin nor amylase X-ray of the pancreas did not reveal any calcification Serum-cholesterol was low (108 mg per 100 ml) Xylose absorption test and glucose-tolerance curve did not reveal malabsorption

Liver-function tests, including estimations of serum-bilirubin, thymol turbidity, thymol flocculation, zinc-sulphate turbidity, alkaline phosphate, serum albumin and globulin, and gamma-globulin, were normal Hæmatological examination was normal

A mecholyl sweat test was carried out, using the technique of Anderson and Freeman (1958) The sodium and chloride concentrations of the sweat obtained were respectively 85 and 71 mEq per litre.

Small-bowel suction biopsy was carried out by the method of Shiner (1957) The specimen (fig 3) showed a normal villous pattern, but an inflammatory infiltrate mainly of plasma cells was present through the lamina propria Swollen goblet cells were extremely numerous, and some of the crypts were filled with granular eosinophilic staining material The right submandibular salivary gland was removed for biopsy Section of the somewhat enlarged gland was within normal limits

Spermatazoa were absent from specimens of seminal fluid. Biochemical studies of the seminal fluid suggested normal prostatic function but very little seminal vesicular function.

Treatment

An attempt was made to control bronchial infection with long-term broad-spectrum antibiotics, and later pancreatic extract was administered. The patient was started on tetracycline 250 mg six-hourly by mouth. He has since produced only 1–2 drachms of mucopurulent sputum daily, cough is much less, effort tolerance has improved, nasal discharge has ceased, and vision has improved. He was then given 'Pancrex 15', a concentrated pancreatic extract, in a dosage of 0 5 g t.d.s with meals Since then he has passed only one or two well-formed stools daily and there is no longer any oily discharge His appetite is much reduced, but despite this he has gained several pounds in weight.

Discussion

In this case a diagnosis of fibrocystic disease of the pancreas is worth considering because of the association of pancreatic achylia with widespread bronchial disease and the suggestive family history Investigation has done nothing to disprove the diagnosis The evidence from the gastrointestinal studies points strongly towards the steatorrhœa being of pancreatic origin Small-bowel biopsy did not show the mucosal changes seen in idiopathic steatorrhœa, but the appearance of mucus-secreting cells and the mucous were similar to those in fibrocystic disease of the pancreas In this respect, the section (fig 3) shows a remarkable similarity to those of small and large intestine demonstrated by Bodian (1952) in his monograph on this disease

It is difficult to suggest a reasonable differential diagnosis, unless the conditions are felt to be unrelated Pancreatic achylia has a number of causes, most of which are unlikely in this patient. Mumps is a rare cause of such selective pancreatic damage Chronic pancreatitis is very unlikely in view of the absence of a history of pain, of diabetes, and of calcification on X-ray

The pulmonary changes are compatible with widespread damage from several causes, but they are not typical of ordinary bronchiectasis in that bronchial dilatation is slight and of unusual distribution In children who have died of fibrocystic disease of the pancreas emphysema is usually much more severe than in the present case However, cases of fibrocystic disease with less severe pulmonary involvement are seen, and in these emphysema is not so prominent. Respiratory function tests in the present case gave similar results to those in children with fibrocystic disease of the pancreas, rather than in adults with emphysema

A good deal of diagnostic reliance is placed on the sweat test in children with fibrocystic disease of the pancreas The figures obtained in the present case are outside the normal range in healthy children (i e, above 70 mEq per litre), but are within the upper limit of values found in a series of normal adults by Anderson and Freeman (1958) The results of this test are as yet difficult to interpret in adults owing to the uncertainty of the range of adult sweat-electrolyte levels

It had been hoped that the resected submandibular salivary gland would show the changes occasionally found in children with the syndrome, but apart from its large size there was nothing unusual about the gland In the great majority of childhood cases, the salivary glands are also normal

Sterility investigations suggest seminal vesicular deficiency, and it is tempting to regard this as possibly associated in some way with fibrocystic disease There is no reported case of parenthood in a proven case of this condition, and it will be of interest to learn whether sterility is usual as more patients reach adulthood

There appears to be no documented case of fibrocystic disease of the pancreas of comparable age to that of the present case Andersen (1958) rejects several on various grounds, but states that she expects genuine older cases to be found We feel that this case reasonably fulfils the required criteria

Summary

A middle-aged man with features of long-standing bronchial infection was found to have chronic diarrhœa.

Investigation disclosed that the chest infection was of unusual type, with widespread bronchial damage. The diarrhœa was due to pancreatic achylia Many swollen mucus-secreting cells were present in a biopsy specimen of the small-intestinal mucosa.

There was a family history of deaths in childhood in brothers and first cousins, in part due to disease of the chest

The patient is believed to have fibrocystic disease of the pancreas, and if the diagnosis is correct this is the oldest reported case

Many people have given assistance, particularly with the investigations, and in this respect we wish to thank the staffs of the clinical research units of both the Royal Children's Hospital and the Royal Melbourne Hospital Dr Ian Wood performed the intestinal biopsy, Dr Bryan Gandevia the respiratory function tests, and Dr Eric McKay the seminal investigations

" It is necessary to avoid the error of supposing that tropical medicine is an entity separate and distinct from medicine in the other regions of the world. It is certainly true that there exist within the tropics diseases of great prevalence and importance that are not found in cooler climates, but these diseases are found superimposed upon a basic disease pattern which is not dissimilar to that seen in advanced Western countries The frontiers of tropical medicine today are set so wide that the doctor is thankful to join forces with the biochemist, the geneticist, the sociologist, the educationist, the agronomist and many other specialists, which is precisely the case with medicine in other climates, and it is not so long ago that what is (significantly) never called 'temperate medicine' had to cope with health problems on a scale almost as vast as that which confronts us in tropical countries"—DR IAN MCGREGOR, *Listener*, Jan. 7, 1960, p 15

Preliminary Communication

RELATION OF FREE CORTICOSTEROIDS IN URINE TO STEROID DOSAGE

IN clinical practice the urinary excretion of 17-hydroxycorticosteroids—i e, 17(OH)CS—is a measure of whether a patient has excess hydrocortisone (cortisol) or is in need of it Experience has shown that excess is accompanied by above-average excretion, and deficiency by below-average excretion Recent studies of the protein binding of hydrocortisone show that the small diffusible fraction determines the clinical effectiveness of hydrocortisone, and that the diffusible fraction does not vary directly with the protein-bound fraction as the blood-level rises [1] This being so, assays of plasma hydrocortisone are not an accurate guide to the effective concentration of hydrocortisone, and it is not likely that the urinary excretion of 17(OH)CS is an accurate guide either

The excretion of free unmetabolised hydrocortisone in the urine may provide a measure of the effective (diffusible) fraction in the blood [2] Because of the recent protein-binding studies this suggestion can be tested, since one can predict from them how much hydrocortisone should appear in the urine if the excretion varies with the level of diffusible hydrocortisone

METHOD

To induce a steadily rising blood-level a normal subject took hydrocortisone daily in divided doses, increasing the dose by 20 mg every two days Twenty-four-hour specimens were collected under toluene, and the excretion of hydrocortisone, cortisone, and total 17(OH)CS was measured

Hydrocortisone and cortisone were measured by the methods of Bush,[3] with minor modifications suggested to us by Dr Bush Total 17(OH)CS was measured by the method of Appleby et al [4]

RESULTS

Fig 1 shows the mean excretion of hydrocortisone, in microgrammes, for each two-day period, and of total 17(OH)CS in milligrammes Except for the last three days' hydrocortisone excretion, the pairs of assays were too close to be depicted separately The rate of increase of hydrocortisone excretion is what could be predicted from the protein-binding studies

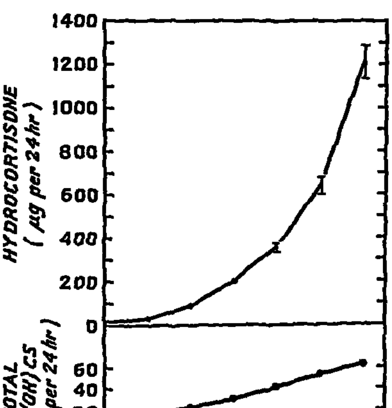

Fig 1—Increase in the absolute and relative excretion of hydrocortisone and total 17(OH)CS at successively higher doses of hydrocortisone

Fig 2, the curve of the excretion of hydrocortisone plus cortisone, is included because the biological significance of free cortisone in the blood is unknown

DISCUSSION

To know just how accurately the urinary free hydrocortisone reflects the diffusible level in the blood we must await more complex studies in which this blood-level is measured over the same period as the urinary levels Nevertheless our findings, which reasonably fulfil prediction, do show great disparity between the estimates from the excretion of free hydrocortisone and those from the excretion of 17(OH)CS metabolites They are consistent with the very considerable evidence that steroids act as catalysts, and that their metabolites result largely from the disposal mechanisms of the liver The rapid rise in effective steroid level as doses in the physiological range are exceeded is consistent with the clinical finding that long-term side-effects increase rapidly with small increments of dosage (e g, prednisolone 7 5→10→12 5 mg)

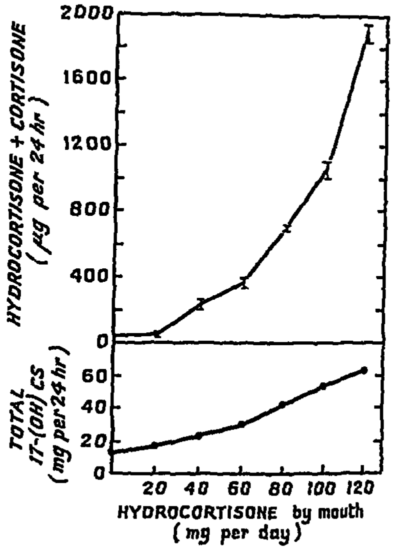

Fig 2—Increase in the absolute and relative excretion of hydrocortisone plus cortisone, and of total 17(OH)CS, at successively higher doses of hydrocortisone

An obvious criticism of urinary assays is that the findings may be upset by tubular reabsorption or excretion Since our study Schedl et al [5] have reported that 80–90% of filtered hydrocortisone is reabsorbed, and that glomerular filtration-rate and urine volume seem to have little effect This is reassuring The absolute figures given above are consistent with 80–90% reabsorption So little hydrocortisone is lost in the free form that, from teleological reasoning, one would not expect to find a purposeful selective reabsorption of hydrocortisone

We conclude that the estimation of free hydrocortisone in urine is a promising means of estimating the effective level of the hormone in the blood, and that it may well prove far more revealing than the measurement of urinary hydrocortisone metabolites

New Inventions

A BAG FOR MEASURING RESPIRATORY VOLUMES

It is often desirable to measure the vital capacity or minute volume of a patient with respiratory insufficiency, but most methods are clumsy, inaccurate, expensive, or not available at the bedside. We have used a small calibrated hexagonal plastic bag (fig. 1), which is made by welding together two sheets of polyvinyl chloride (P.V.C.) $^{10}/_{1000}$ in. (0·25 mm.) thick, and which has a P.V.C. inlet tube of $^{1}/_{2}$ in. (1·25 cm.) bore. The obtuse angles make for easy and complete emptying, since air cannot pocket. The design incorporates a wooden rod of 1 in. (2·5 cm.) diameter at the lower end. When this is rolled up the long axis, the bag becomes wrapped round it, and is therefore emptied completely. A small rubber band can conveniently keep the bag rolled and ready for use. When the outlet tube is occluded, the wooden rod can only be rolled partly up the length of the bag. The distance from the rod to the neck, as measured by the scale on the bag, is an accurate function of the volume of gas contained (fig. 2).

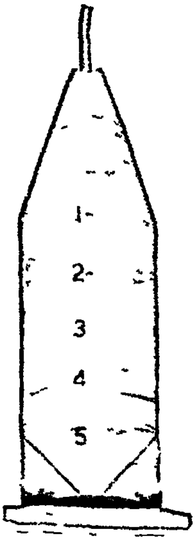

Fig. 1—The bag. The air compartment is outlined in black, and intermediate points on the litre scale have been omitted.

We have measured various respiratory-air volumes, and since, for example, the minute volume of expired gas from a respirator may be many times greater than the vital capacity of a severely disabled patient, we have used two bags of different sizes for different purposes. The larger, which can be used for smaller volumes if accuracy is not of first importance, is 12 in. (30 cm.) wide and the smaller is 8 in. (20 cm.) wide. A convenient total length for each is about 24 in. (60 cm.), including tapers of 8 in. (20 cm.) at the inlet end and 4 in. (10 cm.) at the other.

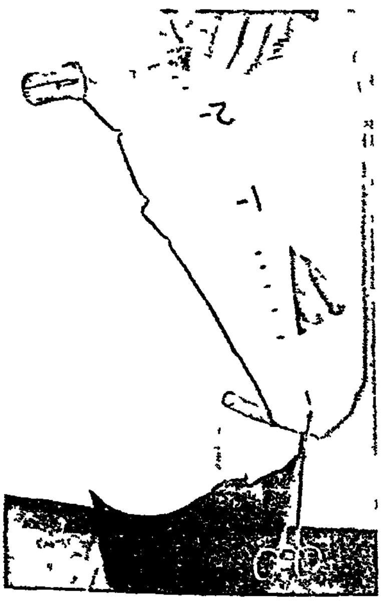

Fig. 2—Measurement of a volume of about 2·6 litres. (Scale simplified for clarity.)

THE BAG IN USE

The basic principle is that the observer should roll up the bag until the part containing gas is fairly tense. We have found it most satisfactory first to roll the bag with both hands, and then to hold the rod in one hand and rest the bag on the other forearm, rolling until the tension feels correct (fig. 2). While maintaining this degree of tension, which is arbitrary, the position of the rod on the scale should be read.

Errors may arise from variations of pressure on the gas, from various degrees of indentation of the bag, and from simple variations in reading the scale. But a series of suitably designed experiments has shown that the results are consistent for any one observer, and that the pressure to which he rolls the bag does not depend on practice. The method described above of handling the bag and reading the scale can be repeated reasonably accurately (table I). Most observations by one observer fall within the range ±2% of his mean estimate. The results obtained by different observers, however, show regular differences. One observer may consistently produce results whose mean is ±3% from the correct value, but such a large error is uncommon. Differences between the results obtained by various observers are largely due to differences in the pressure which they use and the compliance of the bag system. Hence if a particular observer calibrates a bag to his own method of handling, the results show a standard deviation from the mean of less than 2%, for volumes greater than 2 litres (table II).

TABLE I—TWO SERIES OF ESTIMATIONS OF GAS-VOLUME, USING THE LARGER BAG, MADE BY FOUR OBSERVERS AT 4 WEEKS' INTERVAL

Observer	*Series I* 10 observations correct value 8·47 l		*Series II* 5 observations 4 weeks later correct value 8·67 l	
	% error of mean	% range of errors	% error of mean	% range of errors
A	−0·83	−2·01/−0·35	−1·50	−0·3/−2·7
B	−3·30	−4·36/−0·83	−1·73	−2·0/−0·8
C	+0·12	−0·83/−1·53	−1·96	−3·1/−0·8
D	−3·18	−5·56 −0·83	−3·57	−4·3/−3·1

The observers had not used the method before the first observations nor during the 4 weeks interval.

TABLE II—ESTIMATIONS MADE BY ONE OBSERVER USING THE LARGER BAG CALIBRATED TO HIS OWN TECHNIQUE

True value (l.)	8·47	1·86
Mean of 30 estimates	8·42	1·83
% error of mean	−0·59	−1·61
% range of errors	−2·01/+3·90	−1·31/+2·69
S.D. of 30 estimates about mean value (%)	1·33	1·64

The above results apply to the larger bag. The smaller one can be used with similar accuracy to measure smaller volumes. The shape of the taper is such that the difference between 200 ml. and 300 ml. of gas is equivalent to a distance of 1 in. on the scale.

The most satisfactory method of estimating minute volume is to collect and measure the volume of gas breathed in a number of complete respiratory cycles occupying about 60 sec., timing the period accurately (Cooper 1959).[1] One can conveniently draw on the bag a nomogram from which the minute volume can be read without calculation, since, when time is represented transversely (along the axis of the rod), the rod acts as the cursor on the nomogram.

These bags can be cleaned simply by rinsing, but at times they may be contaminated by viscid sputum. Satisfactory readings have been obtained with a bag in which the wooden rod is split in its long axis and held together by countersunk nuts and bolts. The bottom of the bag is not sealed. Thus when the rod is taken apart the bag can be opened for cleaning.

Reviews of Books

The Royal College of Surgeons of England—A History

SIR ZACHARY COPE, F R C S London Anthony Blond 1960 Pp 360 63*s*

THE pillars of the Royal College of Surgeons have a serenity about them which makes it easy for the visitor to Lincoln's Inn Fields to realise that they have stood thus for well over a hundred years and that behind them lie the headquarters of a body whose origin can be traced back for at least four times as long He may find it more difficult to credit that, in their day, these buildings have reverberated with the efforts of the Bow Street runners to separate their dissenting occupants or that, at another time, these doors were barred, by the council of the college, against its own members

The story behind these affairs—and many more memorable and creditable activities—is here related by Sir Zachary Cope, already celebrated as surgeon, historian, and writer For this latest work he has a particular qualification, in that for nine years he was a member of the council of the college The detailed study he has now given of its evolution will be appreciated by historians everywhere—because, despite the college's venerable age and complete records, no such account has previously been published

But Sir Zachary's book is likely to find its keenest readers amongst his colleagues, the fellows and members of the college, and they will learn from it much that is likely to be new to them that when a council meeting ends, each of those who have been present throughout receive a guinea for their pains, that the Speaker of the House of Commons and the First Lord of the Admiralty are both trustees of the Hunterian Collection, and that a former president of the college once petitioned Parliament not to grant a new charter to it.

Even those who have failed in their aspiration to fellowship or membership will derive some pleasure from the book, and they will certainly sympathise with the disappointed Conjoint candidate who, in July, 1920, greeted the news of his rejection by discharging a revolver six times in the Inner Hall, and threatening a college servant And any who have been tempted to condemn the court of examiners as unreasonable should note that this same candidate was given permission to present himself again, only a year later

Coronary Heart Disease

J W GOFMAN, M D, PH.D, professor of medical physics, University of California Oxford Blackwell Scientific Publications 1959 Pp 353 60*s*

THE author has made a distinguished contribution to the study of ischæmic heart-disease by showing that this disorder is associated with an altered physical condition of the lipids in the blood Measurements with the ultracentrifuge show increased quantities in plasma of those lipoproteins which are of low density and so can be separated and measured in a high gravitational field This change is clearly connected with the better-known rise in plasma-cholesterol also associated with the disorder From measurements of the concentrations of various components of the lipoproteins, Professor Gofman calculates an atherogenic index which he claims can be used to measure the risk of an individual to future clinical attacks of ischæmic heart-disease For some years, however, there have been claims that the atherogenic index is, at the best, an expensive substitute for a measurement of the plasma-cholesterol The evidence presented in this book is not such as to make many of the author's opponents change their minds on this point Few hospital laboratories in Britain possess an ultracentrifuge and we do not know of any convincing evidence that the need for one is strong

Much of this book is taken up with discussions of the relations of high blood-pressure, heredity, age, sex, overweight, diet, cigarette smoking, diabetes, and thyroid disease to ischæmic heart-disease These epidemiological studies are not always easy to follow on two occasions the author allows himself to run for over four pages without a fresh paragraph

Professor Gofman is an expert physicist, and there are important biophysical aspects of ischæmic heart-disease, but this book is in some ways disappointing, for one would like to know more about these aspects and less about his disagreements with the biochemists, who after all are studying the same phenomena though from a different angle

A Guide-Book to Biochemistry

KENNETH HARRISON, lecturer in biochemistry, University of Cambridge London Cambridge University Press 1959 Pp 150 17*s* 6*d* (10*s* 6*d* paper-bound)

THIS book is intended to present the bare bones of biochemistry It aims at being useful in schools for telling pupils what biochemistry is about, and to help them to decide whether to take it as one of their university subjects It also hopes to provide an introduction for specialists in other branches of science, and for students beginning to study biochemistry

Advantage is taken of two devices a kind of shorthand which abbreviates elaborate chemical structures in capital letters, such as A T P and D P N, and "flow sheets", whereby the pattern of complicated reactions is demonstrated by following carbon, phosphate, or chemical names through a sequence of changes without constant attention to the intricacies of chemical changes An appendix gives the formulæ of fourteen "carrier" molecules, such as A M P, A D P, D P N, T P N, and U D P G, and discusses them in detail (adenosine monophosphate, adenosine diphosphate, diphosphopyridine nucleotide, triphosphopyridine nucleotide, uridine diphosphate glucose)

Not all of the chapters, which cover energy, enzymes, oxidation, photosynthesis, carbohydrates, fat, protein, and the control of their metabolism, will be equally understood by schoolboys and non-biochemical scientists or doctors, but on the whole the author's aim is achieved In a future edition the statement that mitochondria contain the enzymes synthesising fatty acids should be corrected

Transplantation of Tissues

Vol 2 Editor LYNDON A PEER, M D, clinical and research director, Rehabilitation Center for Plastic and Reconstructive Surgery, St Barnabas Medical Center, Newark, N J Baltimore Williams Wilkins Co London Baillière, Tindall & Cox 1959 Pp 690 160*s*

FOUR years have passed since volume 1 of this large work appeared, and they have been fruitful ones for its subject A growing literature testifies to this, and one of the assets of the new volume is its comprehensive review of both new and established work It covers a much wider field than its predecessor The editor, Dr Peer (he was the author of the first volume), has twelve other contributors P B Medawar on the zoological laws of transplantation, D M. Hume on renal grafts, and Ramon Castroviejo on the cornea speak with the authority one would expect. Blair O Rogers in an interesting section on skin draws from history as well as genetics and immunology Dr Peer's own article is on fat grafts, and it will surprise most readers to find 80 pages devoted to this topic, particularly when 24 were considered sufficient for the cornea Deterling has given as comprehensive a statement on blood-vessel grafts as could be wished for it covers the entire development of this new adjunct to vascular surgery, from the work of Carrel to the uneasy state which now prevails because of the apparent succession of cloth prostheses to the place of choice in preference to homografts Equally valuable are the sections devoted to nerve (the late Sterling Bunnell), endocrine tissue P L Krohn), and tissue culture (Mary Parshley)

This book, filled with countless carefully presented observations and the mature reflections of experts, makes it plain that transplantation still awaits its Fleming, its Banting and Best this "new dimension of accomplishment", as Medawar puts it, is the most important subject facing surgical science today This book will have an important function in admitting more interested readers to a difficult but exciting realm of knowledge, and the guidance it gives may well add further impetus to the search for understanding

THE LANCET

LONDON 13 FEBRUARY 1960

Acute Tubular Necrosis

ACUTE tubular necrosis is the commonest cause of acute oliguric renal failure If the patient does not die in the first few weeks of the illness, virtually complete recovery of renal function ensues,[1–3] and susceptibility to further kidney damage is apparently not increased The management of this condition has greatly improved in the post-war years with the introduction of conservative measures to reduce the rate of clinical deterioration [4 5] and of hæmodialysis by the artificial kidney [6], and a few years ago the results of treatment were giving rise to optimism Thus STRAUSS and RAISZ [7] wrote in 1955 "The mortality in acute tubular necrosis itself can be reduced by a combination of physiologic measures and external dialysis to nearly zero" About this time, however, reports of treatment of acute tubular necrosis in wounded soldiers in Korea [8 9] gave a less satisfactory picture The rate of biochemical deterioration was more rapid in the traumatic cases than in the average civilian patient with little or no tissue damage Injury to voluntary muscle was found to be especially important because there was often a rapid rise of plasma-potassium complicated by severe uræmic acidosis due to transfer of intracellular electrolytes from muscle to the extracellular fluid and plasma Early and oft-repeated hæmodialysis was necessary, whereas non-traumatic cases could often be successfully treated by conservative measures alone. The mortality reported by TESCHAN et al [9] in 51 wounded soldiers with acute tubular necrosis was 53%

Subsequent reports on the treatment of traumatic cases in civilian practice have been equally unfavourable An analysis [10] of 791 cases collected from nine centres showed a total mortality-rate of 43% PARSONS and MCCRACKEN [11] report that of 25 patients with acute tubular necrosis due to complications of pregnancy or parturition only 2 died, whereas of 25 in whom the cause was accidental injury or surgical operation 18 died BLUEMLE et al [12] have analysed 100 consecutive cases of acute tubular necrosis treated in the University of Pennsylvania School of Medicine in the past ten years They subdivide the cases into a "favourable" group, due to transfusion hæmolysis or to obstetrical complications, with a mortality of 27%, an "intermediate" group, due to poisoning with nephrotoxic drugs or to miscellaneous causes, in which 50% died, and an "unfavourable" group, due to accidental injuries or surgical operations, with a fatality-rate of 73% A retrospective analysis of the series reported by SWANN and MERRILL [13] gave an almost identical result.

BLUEMLE et al give a valuable detailed account of the causes of death in their cases They consider that infection was the most important single factor and that this played a major part in 72% of the fatalities Pneumonia and tracheobronchitis were the commonest types of infection, followed by intra-abdominal sepsis and septicæmia Urinary-tract infections, which were common, did not prove immediately fatal in any patient, but in some the infection may have caused permanent renal damage 5 patients are reported to have died from hyperkalæmia before hæmodialysis could be arranged (This should now be a rare cause of death in advanced communities, but most centres equipped for hæmodialysis still find that patients are often transferred for treatment too late—sometimes almost moribund) Non-infective cardiopulmonary complications and disturbances of the central nervous system, including coma and uræmic convulsions, were also of considerable importance Excessive bleeding was troublesome, and sometimes prevented or delayed hæmodialysis As in other studies, the causes of the hæmorrhagic tendency were varied, and included reduction of blood-platelets and deficiency of several plasma-coagulation factors Delayed wound healing was another troublesome complication, and partial or complete dehiscence of abdominal incisions occurred in 5 cases In a further 6 patients fistulæ developed after abdominal operations STEIN and WIERSUM [14] have studied rupture of abdominal incisions from another angle They found that the incidence of dehiscence in abdominal incisions in a single hospital over an eleven-year period was 0 42% The mortality-rate in these patients was 23% In all the fatal cases where adequate information was available, there was postoperative acute oliguric renal failure with severe urea retention and typical tubular lesions at necropsy

In this week's issue Dr LOUGHRIDGE and her colleagues report on the clinical course of uncomplicated acute tubular necrosis due to obstetric and medical causes They record mortality figures similar to those in previous series and have selected the more favourable group of cases for analysis In these the course of the disease was found to be more regular and predictable, and therefore more suitable for statistical analysis, than in the cases due to trauma or surgical operations The modern tendency to restrict fluid intake to 500 ml more than the measurable fluid loss of the previous day is shown to be an improvement on previous methods involving a more generous allowance The average duration of the uræmia was five weeks, but at the end of this period the patients were still invalids incapable of normal activities This series should prove a useful control for a similar analysis of the more serious group

of cases with acute tubular necrosis of traumatic origin It is still uncertain whether the graver prognosis of the surgical cases is due entirely to the associated injuries and consequent increased liability to infection. Possibly the injuries may prolong the uræmia either by continuing renal damage or by increasing the rate of breakdown of endogenous protein to urea and other nitrogenous waste-products

Modern Medicine in Ancient Societies

> "Too often man assumes that he can manipulate nature freely and without consequence; hence the grand effort to wipe out disease"[1]

WHEREAS immense energy goes into the application of new techniques, comparatively little attention has been paid to their secondary effects; and we are only now beginning to think seriously, for instance, about the consequences of introducing preventive and curative medicine to primitive societies In present lifetimes the material standards of most developing countries are unlikely to be raised to those of the West, yet modern medicine—or at least the lifesaving drug—is only around the corner It is encouraging to know that some of the implications of rapid medical improvement, as well as the best ways of achieving it, are now being studied by a team from Cornell University which has been working since 1952 among the Navajo Indians. In a paper, based on his Jenner lecture at St George's Hospital in July of last year, WALSH MCDERMOTT et al[2] describe what is being attempted

The Navajo is the largest of the remaining American Indian tribes, and its culture is remarkably intact. The population of 85,000 is scattered over a vast area (more than 23,000 square miles) of the remote south-western portion of the United States, between the Grand Canyon and the Rocky Mountains—rough country with poor communications and a climate of extremes Lively and vigorous, the tribe is based on the family and not on the village, and the family groups may be many miles from their neighbours. They live in windowless mud huts with earth floors, a central smoke-hole, and no sanitation Most of the adults know no English Although there is a flourishing Navajo religion, an added difficulty for the team is the lack of any written language. Sheep-farming, rug-weaving, and silver-working are the main modes of livelihood, with occasional seasonal work on the railway and farms outside the reservation MCDERMOTT emphasises the interrelation of things

> " the Navajo stay on their ancestral land and raise sheep thus over-grazing the land so that it blows away and is subject to flash floods which make the roads impassable so that the children cannot get to school to learn English so that they cannot successfully compete in the world outside the Reservation so that of necessity they must stay at home and raise more sheep"

The Cornell group have chosen a district of 800 square miles and a population of about 2000 which returns a representative to the tribal council A preliminary survey has shown a birth-rate of 48 7 per 1000 and a crude death-rate of 7·3 per 1000 (the corresponding figures for the United States as a whole are 25 0 and 9 6)

At present, perhaps the best means of bringing medical aid to scattered homesteads in vast undeveloped areas is some form of semi-professional worker, carefully trained to advise on hygiene, perform vaccinations and inoculations, distribute simple remedies, and recognise the illnesses which require a doctor The subassistant surgeon of former days in India was such a person; and so was the old Russian feldsher, who has been retained in the Soviet medical organisation, and still does much of the medical work of the Russian countryside Less ambitiously, the Cornell group intends to use native "health visitors", equipped with a car and radio-telephone, four of whom can be controlled by a single nurse or doctor. The difficulties of course are great the need to transfer concepts from one language to another (particularly when one of the languages is not written), the influence of the traditional medicine-men (though, so far, these have always cooperated with the team), and the danger that when a person is trained in an alien technique he may become as alien as the outsider Even granted good will, enthusiasm, and supervision of the "health visitors", there must still be risks in handing, to people of very little education, the means of life or death As MCDERMOTT et al remark.

> "With today's drugs we can place in the hands of a barefoot illiterate villager more real power to affect the outcome of a child critically ill with, say, meningococcal meningitis, pneumococcal pneumonia, or tuberculosis, than could have been exerted by the most highly trained physician of twenty-five years ago"

But some of the problems can be solved, and some have of course been tackled already in other countries. In the present school year it is hoped to get virtually all the Navajo children into new schools. On the precedent of South Africa, where some of the medicine-men are trained in procedures such as vaccination, perhaps some of the Navajo medicine-men could become "health visitors" Nor are the trained necessarily so alien to their own countrymen Sixty years ago an article on Russian medicine quoted a peasant from a remote district

> The doctor—oh! he's the gentleman's doctor, but the feldsher is the *moujik's doctor*[3]

The team is studying the patterns of primitive life—in particular anxieties, diet, exercise, sleep, and the consumption of tobacco Of the diseases they have seen, some three-quarters have been due to infection (particularly streptococcal and tuberculous) and its sequels (e g, chronic otitis media) gallstones are fairly common, but cancer, hypertension, and myocardial infarction are rare (Though partly explained by the fact that few Navajo reach middle age, the rarity of myocardial infarction is remarkable, and of special interest because the Navajo diet is rich in animal fat) To illustrate how much can be done quickly, the success of an anti-tuberculosis programme may be cited

In 1952 probably some 2–3% of the Navajo had active pulmonary tuberculosis[4] Arrangements were then made by the Government and the Cornell group to have as many as possible of these patients receive chemotherapy in the small reservation sanatorium and in sanatoria outside the reservation. In 1956 the Cornell team began ambulatory chemotherapy and the tuberculin testing of infants and schoolchildren in the project area. All positive reactors were given prophylactic isoniazid for twelve to eighteen months. As in less backward areas,[5] there was the problem of ensuring that patients took their drugs regularly.

---

[1] Gordon, J H *Amer J med Sci* 1958, 236, 337

[2] McDermott, W, Deuschle, K, Adair, J, Fulmer, H, Loughlin, B *Science*, 1960, 131, 197, 280

[3] *Lancet*, 1897, ii, 363

[4] Deuschle, K *Amer Rev resp Dis* 1959, 80, 200

The results from the two programmes were striking. Between 1952 and 1957 mortality from tuberculosis declined by 40%. In the project area, positive tuberculin reactions in children between 5 and 10 fell from 33% in May, 1956, to 22% two years later, while the low incidence of reactions in the school "beginners" class in the autumn of 1958 was even more significant. Of the 49 children only 8 (16%) were tuberculin-positive, and all but 2 of these were already known to be reactors. DEUSCHLE[4] regards this and the absence of miliary or meningeal disease in young children as evidence that tuberculosis is coming under control in the community.

In theory, a developing community might be able to enjoy the "best of both worlds" during the phase when the benefits of modern medicine and of traditional culture are seen together, and there are signs that this is happening to the Navajo. When this period is over, however, they will not necessarily develop the present Western pattern of disease, for, as GORDON[6] says,

> "A new influence introduced into the (ecological) system can disrupt the established balance, and set off a new succession whose ultimate end is difficult to predict."

Answers to some of the questions raised in this investigation will be applicable to developing countries outside North America. The Navajo microcosm, situated inside the richest economy in the world, cannot accurately represent the macrocosms of present-day Asia and Africa, but they have many things in common. In particular, the possibility of real harm from too rapid or too enthusiastic technological change must never be forgotten anywhere. MCDERMOTT quotes Mr GEORGE KENNAN:[7]

> "Wherever the authority of the past is too suddenly and too drastically undermined—wherever the past ceases to be the great and reliable reference book of human problems—wherever, above all, the experience of the father becomes irrelevant to the trials and searchings of the son—there the foundations of man's inner health and stability begin to crumble, insecurity and panic begin to take over, conduct becomes erratic and aggressive. These, unfortunately, are the marks of an era of rapid technological or social change."

Annotations

PRIVATE PATIENTS IN THE NATIONAL SCHEME

THE Government are being strongly pressed to allow practitioners to prescribe National Health Service drugs for their private patients. The case is arguable, and it is argued with conviction by many who believe in revival of private practice as a remedy for current ills. Everybody, indeed, must see something harsh in a system which says that, because a person prefers to get his medical help from a doctor outside the National Health Service, or to consult an N.H.S. doctor privately, he cannot have the medicines which, as a taxpayer, he has helped to provide.

The British Medical Association has long maintained that he ought to have them, but it recognised that safeguards would be required before purely private doctors could distribute public property. Accordingly, in December, 1958, it agreed that private patients wanting to use N.H.S. drugs should be registered on a list with the local executive council, and that, in respect of them, private doctors would submit to the same code of conduct and penalties as apply to their N.H.S. colleagues. Unfortunately, simple though this solution sounds, it is not really simple at all. For, though the doctors concerned might continue to think of themselves as private, they would in point of fact be entering the Health Scheme—and entering it without accepting payment by capitation. Even though the patient would be paying his doctor privately, the arrangement would amount to Government recognition of the fee-for-service system.

For our part we trust that, before acting on such a plan, the Government will look at more than its financial implications. Much importance has rightly been attached to the principle that, within the National Health Service, medical privileges cannot be bought. (The apparent exception—the private bed in a hospital—is not really an exception at all: the patient in a pay-bed is paying at least the full cost of his treatment, and, though the bed, with services, are rented to him by the N.H.S., he is in fact being treated at his own cost by his own doctor, outside the service.) The proposal now made is that, *within* the national scheme, patients, by paying fees, shall be able to buy the doctor's time, and the convenience of access to him, which are so important a part of good personal care. Since the commonest criticism of N.H.S. general practice today is that it often fails to provide these things, a great many people might be willing to buy them. Yet we all know that good personal care ought to be provided for everybody who needs it—not sold. Surely the last thing we should now do is to establish within the service a group of people who are engaged in selling care of a higher standard, and who therefore have a vested interest in preserving the defects of ordinary medical care? What we need to do, on the contrary, is to give all practitioners a vested interest in getting rid of those defects.

If the capitation system of payment is really a bar to the necessary improvement, let us change it. But whatever else we decide on, do not let us have within the national scheme two levels of medical attention—a new and better one for those who consult their doctor privately, and another for those who do not.

STEROIDS AND ECZEMA

DERMATOLOGISTS can count among their blessings the accessibility of the skin, which enables them to paint, anoint, or spray their patients with steroids. The effectiveness of these measures in many cases of eczema is manifest, and Nordin,[1] who has studied the toxicity of steroids, advises dermatologists to content themselves with topical application whenever possible. It would be premature, however, to assume that topical application never carries a risk, though it is clearly safer than systemic treatment. Nordin found up to 8% mortality attributed to systemic steroid treatment in 11 reported series, one of which[2] concerned 200 patients who suffered from a wide variety of dermatoses including pemphigus, of whom 22 had serious complications and 7 died But the significance of these findings is doubtful, since no distinction was made between those on high life-saving doses and those on small suppressive ones

---

[1] Nordin, B. E. C. *Brit. J. Derm.* 1960, 72, 40.

The lives of patients on systemic steroid treatment are threatened in various ways[3] their gastrointestinal tracts may perforate or bleed they are prone to intercurrent infections, whose symptoms are masked, or to recrudescence of latent infection, they are probably particularly susceptible to thromboembolic catastrophes, and they are liable to a number of other potentially serious complications In view of this catalogue of iatrogenic disaster and suffering it is natural that Cronin and Wells[2] were extremely reluctant to treat with systemic steroids atopic eczema (Besnier's prurigo), which is not a fatal disease Nevertheless Sneddon[4] felt from his experience that the dangers of suppressive doses might have been exaggerated He has given steroids to 26 patients with atopic eczema, selected from 500 for their severity, their failure to respond to other treatment, including topical steroids, and their freedom from tuberculosis, hypertension, and dyspepsia The treatment has continued for periods of up to 4¹/₂ years, and the daily maintenance dose was usually between 5 and 15 mg of prednisolone In 19 patients the result was good and in 5 fair No serious complications arose, but most patients have become plumper Infection or emotional stress required a temporarily increased dose of steroid, and the risks of surgery have been partly met by issuing a warning card to all patients and urging them to produce it if they consult a surgeon

The patients improved in personality and coped with life more easily, a change reflecting perhaps the great influence of the dermis on the psyche, as well as the heavy burden of cutaneous misery which such patients carry Lamont,[5] who reported a somewhat similar series, concluded that the prospect of having to continue treatment indefinitely might make the physician prefer other measures But it seems that this method might well help selected patients with atopic eczema as nothing else could If further study confirms its good effects and comparative safety it could truly be said that the disease was worse than the effects of suppressing it. Until then it would be wise to remember Sneddon's final sentence "   some harmful effects may yet arise and treatment should not be embarked upon lightly or in the absence of adequate facilities for close supervision "

COLD-FOOT SYNDROME

THE typical pain of myocardial infarction may be overshadowed by syncope, shock, vomiting, or dyspnœa, but Wood[6] believes that only 5% or less of patients who are carefully questioned deny the presence of pain or some oppressive sensation in the chest during the acute attack, and Roseman[7] could discover only 5 entirely painless infarcts in a series of 220 patients On the other hand the observations of Stokes and Dawber[8] and of Weitzman and Smith[9] show that myocardial infarction can apparently occur without any symptoms and be completely silent Infarcts complicating surgical operations are particularly liable to be overlooked[10,11] because pain is often suppressed by anæsthesia or analgesic drugs,[12] and the picture may be one of shock or persistent hypotension

Frank[13] has described the syndrome of "cold foot", which may be the presenting sign of an otherwise silent postoperative myocardial infarction According to Frank the discovery in the postoperative period of a cold foot on one side, often numb or painful, associated with absent arterial pulsation and with ischæmia on elevation, almost invariably indicates myocardial infarction if the heart rhythm is normal and murmurs are absent The syndrome is, of course, the consequence of arterial embolism in the leg, and, as Haimovici[14] has shown, the vast majority of emboli originate in the heart less common causes are dislodgment of atheromatous aortic plaques, thrombi arising in the pulmonary veins, and, very rarely, paradoxical embolism through a septal defect Primary arterial thrombosis is unlikely unless there is pre-existing vascular disease in the lower limbs Consequently if atrial fibrillation, rheumatic heart-disease, or bacterial endocarditis can be excluded, recent myocardial infarction is the probable cause Frank has detected the syndrome in 3 patients, 5, 7, and 13 days after abdominal operations in all 3, electrocardiography confirmed recent infarction Like Wasserman et al[12] he believes that anæsthesia or postoperative analgesics may prevent appreciation of the pain of myocardial infarction, but he also points out that when pain is felt it may be wrongly attributed to the discomfort of an abdominal wound

THE ALBEMARLE REPORT

THE fundamental and inescapable conflict in teenagers stems from the fact that biological maturity is reached so much sooner than social fulfilment There is nothing new in this What is new is the influence of the changing pattern of our culture—especially the mass media of communication The resulting strains have thrown into relief the difficulties of the years of transition The challenge to society is full of opportunities

Enthusiasm runs through the fascinating report of the Albemarle Committee,[15] published last week This committee was set up by the Minister of Education in 1958 with the following terms of reference

> "To review the contribution which the Youth Service of England and Wales can make in assisting young people to play their part in the life of the community, in the light of changing social and industrial conditions and of current trends in other branches of the education service, and to advise according to what priorities best value can be obtained for the money spent."

In critical terms the report notes the failure of successive Governments to provide the means of bringing the youth service properly to life Reaching only one teenager in three its chief strength has been voluntary help In 1957–58 for each £1 the Government spent on education only 1*d* was available for the youth service Small wonder that its development has been haphazard and that its present condition gives rise to anxiety Whether or not it is "dying on its feet" the committee acknowledges that it is "in a state of acute depression" To the difficulties caused by lamentably inadequate money, drab and unimaginative premises, and a catastrophic shortage of adult helpers with the right training and outlook have been added the effects of "the bulge", the ending of National Service, and the social significance of young people with £3 or more spending money a week in their pockets. Against this background, and aware of a "new climate of crime and delinquency", the committee proclaims and justifies a belief in the immense contribution a youth service can make. This contribution can be made only if the service is expanded and continuously nourished: meanwhile we must rely on short-term, emergency "blood-transfusion" methods.

[15] Ministry of Education The Youth Service in England and Wales Cmnd 929 H M Stationery Office 1960 Pp 135 *6s*

The four great needs are an imaginative and vigorous approach, money, greatly improved premises, and a large increase in trained workers. The committee proposes the establishment of a Youth Service Development Council, numbering not more than a dozen, to advise and help the Minister. A ten-year development programme, starting this year, is recommended; the first half would be devoted to catching up with events, and the second to establishing a permanent structure on firm ground. Local education authorities are recognised as having a crucial role in the growth of what, after all, is part and parcel of full education for living. Arrangements for providing the necessary leaders are considered in detail. A proposed emergency training college would increase the present force of 700 full-time leaders to a provisional 1300 by 1966. Part-time workers, both paid and voluntary, clearly have an important part.

If these recommendations are implemented there will be real grounds for hoping that the needs of the young generation can be met constructively. Implicit in the committee's approach is the conviction that the Government really does intend to make the youth service adequate, and the Government's acceptance of the main proposals is encouraging.

PSEUDOMONAS AND POLYMYXIN

ONLY a concerted hospital policy, such as that initiated by Barber and her colleagues[1] at Hammersmith Hospital, is likely to stem the increase of resistant strains of staphylococci in our hospitals. The shadow of a further danger—an increased incidence of gram-negative infections, particularly with *Pseudomonas pyocyanea*—was cast by the results of the twenty-two-year survey conducted by Finland and his colleagues at the Boston City Hospital,[2] where there has been a sixfold increase in gram-negative septicæmias since the introduction of antibiotics. The situation is similar in British hospitals, as is pointed out on a later page of this issue by Dr Roger Williams and his coworkers, who noted an upsurge of *Ps pyocyanea* infections in Hammersmith Hospital during 1959. Whereas in the first quarter of 1958 only 9 patients were known to have this organism in their sputum, it was found in the sputum of more than 60 patients during a similar period in 1959. In one general medical ward pseudomonas infections were responsible for 5 deaths, and, in addition, sporadic cases of localised infection and of septicæmia arose throughout the hospital. Poor resistance undoubtedly contributed to the 5 deaths, for 2 patients were leukæmic, 1 had agranulocytosis, another was in respiratory failure, and the 5th was receiving long-continued oral corticosteroids on account of hæmolytic anæmia. But Williams et al. suggest that the increase may also be related to the doubled consumption of tetracycline and other broad-spectrum antibiotics.

The only antibiotic that combats pseudomonas infection really effectively is polymyxin. This was isolated independently in Britain[3] and in the United States[4,5] from *Bacillus polymyxa*, and in this country was originally known as 'Aerosporin' (its present trade name). It is now available as polymyxin B sulphate powder in vials containing 500,000 units. It may be given by mouth and by intravenous, intramuscular, intrathecal, subconjunctival, and intrapleural routes. There are various topical preparations, and a 0.1 to 1.0% saline solution may be used to irrigate sinus tracts. Polymyxin, which is not absorbed from the gut, may be given by mouth for bowel infections which do not respond to sulphonamides, streptomycin, or neomycin. Since it does not affect the gram-positive intestinal flora, monilia and other fungi do not emerge as dominants. For systemic infections, it is administered intramuscularly in a dose of 20,000 units per kg daily, an average dosage for adults being 250,000 units four-hourly. Because of pain at the site of injection, it should be administered with procaine and the site frequently changed. During treatment with polymyxin, the urine should be examined daily for albumin and casts, and the blood-urea level should be estimated twice weekly as the drug is potentially nephrotoxic. The indication for its use in severe infections that resist other antibiotics usually outweighs the risk of toxicity. This risk has hitherto prevented its widespread use: which can now be counted as a blessing, for otherwise *Ps pyocyanea* might not be still sensitive to the drug. Polymyxin should on no account be used for the treatment of trivial hospital infections.

CONGENITAL MALFORMATIONS

FROM many sides, the pathogenesis, the possible prevention, and the treatment of congenital malformations are getting more and more attention: as postnatal infections come under control, what has been called prenatal pædiatrics is gaining in relative importance. The time is ripe therefore for the first International Congress on Congenital Malformations, and we are glad that it will be held here in London next July.

The honorary presidents are to be the Hon. Basil O'Connor and Sir Geoffrey Marshall, and the general chairman Prof. J. D. Boyd, of Cambridge. Meeting at Church House, Westminster, on July 18, the congress will have a theme address from Dr George W. Corner, and will spend five days on sessions entitled: Incidence, Intrinsic Factors (genetics), Extrinsic Factors (environment), General Developmental Mechanisms, Abnormal Developmental Mechanisms, Maternal-Fœtal Interactions, Physiological and Medical Problems, and Perspectives. The executive secretary and treasurer of the congress is Mr Stanley E. Henwood, and his office is at 67, New Bond Street, London, W.1.

The report of the Royal Commission on Doctors' and Dentists' Remuneration will be published on Feb. 18.

Prof. E. J. WAYNE has been appointed chairman of the clinical research board of the Medical Research Council in succession to Sir Geoffrey Jefferson, who has retired after a six-year term of service as first chairman of the board.

Pseudomonas pyocyanea is well known as a relatively avirulent secondary contaminant of superficial wounds and burns, but more serious infections may occur, particularly in infants or in adults whose resistance is weakened by other disease This organism tends to be resistant to the commonly used antibiotics, and with the widespread use of these agents there is some evidence that the incidence of infection with *Ps pyocyanea* is increasing.

Yow (1952) traced 56 examples of infection due to *Ps pyocyanea* or proteus during or following antibiotic therapy over a two-year period. On analysing the routine cultures received in the bacteriology department during this time he found that the incidence of *Ps. pyocyanea* had risen from 15% of the gram-negative bacilli isolated to 30% In children with mucoviscidosis Garrard et al (1951) observed that the decrease in frequency of staphylococcal infections was accompanied by an increase in those due to *Ps pyocyanea.*

During the past year we have experienced in this hospital a disturbing incidence of cross-infection with *Ps. pyocyanea*, and we draw attention here to some of the problems involved In one general medical ward alone, pseudomonas infection was responsible for 5 deaths. These are described together with studies of the probable source of infection and mode of transmission

Case-reports

Only a brief account of the clinical course is given as the main bacteriological and pathological findings are shown in table I

Case 1.—A man of 22 was admitted in May, 1958, with acute leukæmia After three weeks' treatment with 6-mercaptopurine the white-blood-cell count had fallen to 1800 per c mm (polymorphs 5%) He then developed a fever up to 104°F and signs of bronchopneumonia, the sputum growing *Ps pyocyanea* in pure culture There was no response to antibiotics (including streptomycin) and he died three weeks after the onset of fever.

Case 2.—A man aged 54 was admitted in July, 1958, with polyarthritis, fever, and agranulocytosis, this last being attributed to phenylbutozone which he had been given two months earlier Although the arthritis responded to salicylates the fever continued, and a chest X-ray showed pneumonic shadowing in the left upper zone There was some response to antibiotics (penicillin and streptomycin) and prednisolone, but when the antibiotics were discontinued the fever recurred Finally at the beginning of August numerous papular skin lesions appeared over the trunk and limbs, many of them became nodular with dusky red hæmorrhagic centres increasing in size up to 1 in in diameter At this stage *Ps pyocyanea* was isolated The patient died on Aug. 10, three weeks after admission.

Case 3.—A 59-year-old man, a known case of chronic lymphatic leukæmia, was readmitted in October, 1958, with acute cholecystitis The white-cell count on admission was 4000 per cm (polymorphs 10%) His symptoms subsided rapidly with antibiotics (tetracycline and erythromycin) but he then developed a sore throat followed a few days later by pseudomonas septicæmia This responded initially to streptomycin, but later the fever recurred and laparotomy was performed This revealed an empyema of the gallbladder which was drained, but the fever continued and despite systemic polymyxin he died three days later

Case 4.—A man of 50 with a long history of chronic bronchitis and emphysema was admitted in December, 1958, with an acute exacerbation After an emergency tracheostomy and bronchial aspiration treatment was continued with intravenous hydrocortisone and antibiotics (penicillin and streptomycin) He improved dramatically at first but on the morning of the third day after admission his temperature rose to 104°F *Ps pyocyanea* was now present in the sputum, and he died later the same day

Case 5.—A man, aged 79, with acquired hæmolytic anæmia had been maintained on prednisolone (20 mg daily) since June, 1957 He was readmitted in September, 1958, with fever and a mass in the right lung presumed to be a carcinoma He was treated with radiotherapy and antibiotics (tetracycline and novobiocin) but developed pseudomonas diarrhœa This did not respond to neomycin, and profuse watery diarrhœa persisted until his death in peripheral circulatory failure on Dec 11

MICROSCOPICAL FINDINGS

The histological appearances of the septicæmic lesions in the first 3 cases were basically similar with an area of central necrosis, in which traces of pre-existing structure remained, surrounded by a narrow inflammatory zone

TABLE I—BACTERIOLOGICAL AND PATHOLOGICAL FINDINGS IN 5 FATAL CASES OF PSEUDOMONAS INFECTION

Case no	Pseudomonas cultures during life							Necropsy cultures (pseudomonas)	Relevant postmortem findings
	Specimen	Antibiotic sensitivity pattern							
		P	STR	T	C	N	Poly		
1	Sputum	R	R	R	R		S	Liver, lungs, kidneys	Multiple small septic infarcts in liver, lungs, and kidneys
2	Blood Skin biopsy	Not done "						Lungs	Multiple firm nodules in lungs, small abscesses in kidneys; multiple skin nodules
3	Throat swab		S		R		S	Pus in paracolic gutter	Acute cholecystitis, peritonitis; small abscess in prostate; multiple small nodules in pleura, and two larger ones in right upper lobe
	Blood (1st episode)		S				S		
	Blood (2nd episode)		R	R	R	S	S		
	Empyema pus		R	R	R	S	S		
4	Bronchial aspirate	R	R	R	R		S	Right lung	Acute bronchitis; confluent bronchopneumonia on right side
5	Stool		R		R	S	S	Not done	Numerous yellow ulcers up to 0 8 cm in diameter throughout large intestine

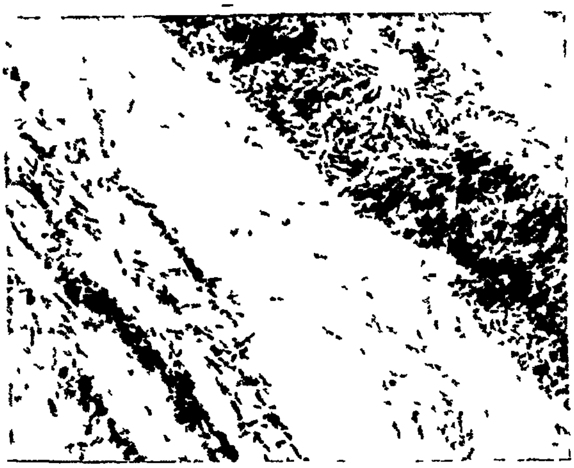
* Present address Medical Unit, Royal Free Hospital, Gray's Inn Road, London, W C 1



High-power view of the wall of an artery adjacent to a pulmonary lesion in case 1 Innumerable bacilli are seen in the artery wall, and small numbers are present in the antemortem thrombus in the dilated lumen (lower left) (Acid fuchsin/picric acid ×950)

containing relatively few polymorphs and much granular debris Gram-negative bacilli were present in the periphery of the lesions and were also seen in very large numbers in the walls of adjacent small arteries (see figure) Some of these were occluded by antemortem thrombus, and in the 1st case a small mycotic aneurysm was found near one of the pulmonary foci The skin nodules in case 2 showed a similar histological picture to the visceral lesions, and numerous bacilli were present in the wall of an adjoining artery The lung lesions in case 3, though similar in distribution and histological structure to those in the first 2 cases, did show some surrounding fibrosis, and it seems likely that these were the result of a previous septicæmic episode (particularly as shadows corresponding to the site of these had been noted in a chest X-ray taken six months before death when the patient was admitted with pyrexia of unknown origin)

In the other 2 cases there was no evidence pathologically of septicæmia In case 4 the bronchopneumonia was remarkable on microscopy for the poor cellular reaction and the numerous gram-negative bacilli in the alveolar exudate Similarly in case 5, despite the widespread ulceration, there was only a slight cellular reaction consisting mainly of plasma cells

Sources of Infection

Infection with *Ps pyocyanea* was not restricted to this one ward, and sporadic cases both of localised infection and of septicæmia occurred throughout the hospital during the year We have described only those cases occurring in the one ward as more information is available there regarding the mode of transmission and possible sources of infection

It seems likely that infection was airborne, for bacteriological studies showed a high concentration of *Ps pyocyanea* in the air Also pneumonic signs were present at an early stage in cases 1, 2, and 4—suggesting a portal of entry via the respiratory tract, and in case 3 the organism was first demonstrated in a throat swab In keeping with this mode of transmission the main source of infection appeared to be sputum Table II shows details of all the patients in the ward during the year who had sputum from which *Ps pyocyanea* was isolated These were mainly cases of chronic respiratory disease, and the organism appeared in the sputum as they were improving clinically after a course of broad-spectrum antibiotics 4, however, had not been treated with antibiotics Although in these the organism was cultured from the first specimen examined, this had not been sent until several days after admission, so the infection may well have been acquired in the ward It can be seen from table I that apart from February, March, and April there were always one or two patients in the ward with sputum containing *Ps pyocyanea* The first of the patients who died later of pseudomonas septicæmia was admitted soon after a patient with bronchiectasis whose sputum consistently yielded a heavy growth of this organism

It is apparent from the varying antibiotic sensitivity pattern of the organisms isolated (tables I and II) that the infections both in the fatal cases and in the patients with respiratory disease could not be attributed to a single strain and probably several were involved

Discussion

The first 3 cases show many of the distinctive clinical and pathological features of pseudomonas septicæmia Although in case 1 a positive blood-culture was not obtained in life, there were at necropsy widespread septicæmic lesions from which *Ps pyocyanea* was cultured in pure growth Fraenkel (1917) originally stressed the tendency of this organism to multiply in the walls of small blood-vessels, producing acute inflammatory arteritis Secondary thrombosis leads to arterial occlusion and the formation of small infarct-like areas of necrosis, which were such a striking feature of the present cases Characteristic skin lesions may occur in pseudomonas septicæmia and may be of help in early diagnosis These (as in case 2) begin as macules or papules and later form round indurated areas with black necrotic centres from which the organism

TABLE II—DATA ON ALL THE PATIENTS IN THE WARD DURING THE YEAR WHO HAD SPUTUM FROM WHICH *Ps Pyocyanea* WAS ISOLATED

Patient	Diagnosis	Present on admission	Date first isolated	Previous antibiotics	Growth	Antibiotic sensitivity pattern					
						P	STR	T	C	Poly	Sul
A	Chronic bronchitis	No	Jan 13	Chloramphenicol	++		R	S	S		
B	Bronchiectasis	No	May 14	Penicillin, chloramphenicol, tetracycline	+++	R	S	R	R	S	R
C	Leukæmia	No	June 16	Tetracycline and novobiocin	++	R	R	R	R	S	S
D	Lung cancer		June 23	None	+		S	R	R		
E	Chronic bronchitis		July 12	None (during this admission)	++		S	R	R	S	
F	Lung abscess	No	Aug 7	Tetracycline and novobiocin	++		S	R	R	S	
G	Chronic bronchitis	No	Sept. 9	Novobiocin and chloramphenicol	+++		S	R	R	S	
H	Mitral stenosis		Sept. 9	None	++		S	R	R	S	
I	Lung abscess	No	Oct. 11	Erythromycin and novobiocin	+	R	S	R	R	S	R
J	Asthma		Oct. 18	None	+++		S	R	R	S	
K	Chronic bronchitis	No	Oct 22	Chloramphenicol and novobiocin	+++			R	S		
L	Lung cancer	No	Nov 11	Tetracycline and novobiocin	+++		S	S			
M	Cardiac infarction		Nov 19	None	+		S	R			
N	Pneumonia		Dec. 5	Penicillin, streptomycin, chloramphenicol	++	R	R	R		S	
O	Bronchiectasis	No	Dec. 15	Tetracycline and novobiocin	++		R	R	R	S	R
P	Chronic bronchitis	No	Dec. 31	Tetracycline and sulphonamide	++		R	R	R	S	S

P=penicillin. STR=streptomycin. T=tetracycline. C=chloramphenicol Poly =polymyxin. Sul =sulphonamide. R=resistant S=sensitive can easily be cultured In a recent series of 23 cases of pseudomonas septicæmia (Forkner et al 1958) skin lesions were present in 9

In the other 2 cases the infection remained localised and bloodstream invasion did not occur In case 4 secondary infection with *Ps pyocyanae* was probably responsible for the clinical deterioration after the earlier response to treatment In case 5 the severe diarrhœa undoubtedly contributed to death Although *Ps pyocyanea* may be isolated occasionally from routine stool cultures, the number of organisms is small and, in those cases where tissue invasion occurs with ulceration of the mucosa, as in this patient, large numbers are seen, at times as many as 50–75% of the colonies isolated are of this organism (Stanley 1947)

Each case had previously been treated with broad-spectrum antibiotics This is in keeping with the role of *Ps pyocyanea* as a secondary or superinfecting organism Forkner et al (1958) found that 77% of pseudomonas septicæmias occurred in patients receiving broad-spectrum antibiotics, whereas only 33% of those due to staphylococci occurred under such circumstances Experimentally, in mice both cortisone and radiation increase the susceptibility to pseudomonas septicæmia (Ross 1956, Millican et al 1957), and there is suggestive evidence in man that anti-metabolite administration may be another predisposing factor (Forkner et al 1958) All our cases had received corticosteroids, and case 1 and 3 antimetabolites, although in case 3 this was many months previously

The occurrence of a normal or low white-cell count in both localised and bloodstream infections with *Ps pyocyanea* has been recognised since 1899 when Ghéorghiewsky claimed to have found a leucocyte-destroying ferment in cultures of this organism and Brill and Libman remarked on the absence of leucocytosis in 2 cases of pseudomonas septicæmia Later, several workers (Lovett 1924, Linthicum 1927, Dasse 1928) isolated this organism from the local lesions and occasionally from the bloodstream of some cases of agranulocytic angina and showed experimentally in guineapigs that it had a direct lytic effect on leucocytes and possibly also an inhibitory effect on their formation in the bone-marrow On the other hand, patients with low white-cell counts are abnormally susceptible to infection and may be particularly liable to pseudomonas septicæmia Forkner et al (1958) found that *Ps pyocyanea* was the most frequent bacterial cause of death in leukæmia and the second most frequent cause of septicæmia Many factors other than a low polymorph-count may, however, contribute to the diminished resistance in acute leukæmia, including abnormal antibody response and altered phagocytic properties of the leucocytes (Silver et al 1960) 2 of our patients had leukæmia and the 3rd marrow asplasia probably secondary to phenylbutazone toxicity, and in all 3 the neutropenia preceded the septicæmia In a fatal case of pseudomonas septicæmia recently in one of the surgical wards, the white-cell count dropped to 2200 per c mm on the fourth postoperative day, but by the time of death, two days later, it had risen to 8000 per c mm

The high mortality of pseudomonas septicæmia is of course related as much to the underlying disease as it is to the superimposed infection All but 2 of the 22 fatal cases reported by Forkner et al (1958) had malignant disease Other series which include cases with less serious underlying disease have a lower mortality (Martin et al 1954) The majority of strains of *Ps pyocyanea* are sensitive only to polymyxin or neomycin Unfortunately, both these drugs are toxic when administered parenterally, although if careful attention is paid to dosage this risk can be largely averted Jawetz (1952) used polymyxin B in a dose of 2 5 mg per kg body-weight for six days in 35 patients with pseudomonas infections over a two-year period without any nephrotoxic effects, but even when this drug is given in pseudomonas septicæmia the result may be disappointing In the series reported by Forkner et al (1958) 9 cases were treated with polymyxin but none improved although in 3 the blood-culture became negative Occasional strains are also sensitive to streptomycin, but resistance usually develops rapidly as in case 3 of the present series

There seems to be no doubt that the patients reported here acquired their infection after admission to hospital Little attention has previously been paid to the problems of cross-infection with this organism in medical wards Forkner et al (1958) studied the incidence of septicæmia in 13 patients with leukæmia treated in the same unit over a twenty-month period They found that septicæmia due to *Ps pyocyanea* tended to occur in small groups in contrast to the random distribution of other bacterial septicæmias, though the factors responsible for this were not clear In an outbreak of infantile diarrhœa in a children's ward (Florman and Schifrin 1950) indirect spread via nursing staff was thought to have occurred as the organisms were isolated from the hands of two nurses who shortly before had handled children with positive stool-cultures An airborne mode of transmission was considered likely in a series of cases of pseudomonas meningitis and penetrating head injuries reported by Botterell and Magner (1945) as a high concentration of *Ps pyocyanea* was found in the air of the wards, all of which were over-crowded

The importance of sputum as a reservoir of infection with *Ps pyocyanea* is shown by the present studies The appearance of this organism in the sputum of the majority of the patients, described in table II, was not accompanied by any clinical signs of infection Nevertheless, it is probably from these patients that the more serious infections in susceptible subjects originate They constitute in this hospital a serious and increasing problem In the first quarter of 1959 there were more than 60 patients with *Ps pyocyanea* in their sputum, whereas during a similar period of 1958 there were only 9 It is tempting to relate this increase to the greater use of tetracycline and other broad-spectrum antibiotics, the consumption of which has nearly doubled over the past year

Various measures may help to prevent cross-infection Clearly the use of broad-spectrum antibiotics should be limited as far as possible Patients with this organism in their sputum should be taught to cough directly into a sputum pot containing a suitable disinfectant such as 'Sudol' which has the same bactericidal spectrum as 'Lysol' without its irritant effect Treatment with inhalations of polymyxin (25,000 units) and neomycin (5 mg) given four times a day through a Wright nebulizer is sometimes followed by disappearance of the organisms from the sputum, but in our experience systemic polymyxin is necessary in those with a heavy growth Ideally these patients should be isolated, but this has proved difficult owing to the numbers involved A more practical measure is to isolate patients with leucopenia from any cause, who appear to be particularly at risk from cross-infection with *Ps pyocyanea*

Summary

Cross-infection with *Ps pyocyanea* materially contributed to 5 deaths in one ward in 1958

Predisposing factors appeared to be a low white-blood-cell count and previous treatment with corticosteroids and broad-spectrum antibiotics

The infection was apparently airborne, and the main source was the sputum of certain patients with chronic respiratory disease.

The frequency of infection with this organism is increasing

We would like to thank Dr J G Scadding and Dr P Hugh-Jones under whose care these patients were admitted for permission to publish this report We are indebted to Mr J Griffin and Miss G Fisher for histological assistance, and to the bacteriology department for help and particularly to Dr Mary Barber for advice and encouragement

PRESERVATION OF MEDICAL RECORDS

A Memorandum by the British Records Association *

THE medical profession is uncomfortably familiar with the proliferation of papers which modern methods of office administration produce The resulting accumulation of papers too often provokes periodic indiscriminate destruction, in which records of value and interest, often of some age, may disappear, along with masses of modern ephemeral material To avoid the ill-effects of unregulated destruction the Association has published memoranda stating general principles for the disposal of records such as are described in its Memorandum no 7, *Modern Records, what may we destroy?*

Since the National Health Service was instituted, certain classes of medical records—e g, those of hospitals and hospital administration—come under the control of the Minister of Health and are subject to the statutory arrangements for public records The Ministry issues directions about their preservation and destruction, which are drawn up in consultation with the Public Record Office The medical records accumulated in health departments of local authorities will, in general, be covered by the arrangements existing within each authority for the preservation of departmental records The following advice is, therefore, primarily directed to individual practitioners, voluntary hospitals, and other organisations or persons whose records are not covered by the preceding arrangements

Records may be classed for the purpose of preservation as those of the distant past, those of the immediate past, and present-day records A convenient division between the distant and immediate past is afforded by the Medical Act, 1858, before which no compulsory system of registration of medical practitioners was enforced. Present-day records may be regarded as beginning with the National Insurance Act, 1911 All records before 1858 should be kept and none of those relating to the period 1858–1911 should be destroyed before advice has been obtained. As regards documents later in date than 1911, the pamphlet *Modern Records, what may we destroy?* provides, in general, adequate guidance There are, however, two kinds of record which call for special consideration.

First, there are the records of individual doctors Details of how practices were run, how patients were referred to the doctor, how many he saw in a day, &c., are very difficult to find. Therefore visiting-list books, letters giving details of consultations, and diaries containing professional rather than personal matters, should be looked for and, if possible, preserved. They are, in general, the kind of thing that tends to be destroyed as being apparently of no interest.

Then there is the clinical note, a kind of record peculiar to medicine, of which, over the years, there may be such accumulation that their preservation in entirety is a matter of some difficulty † But there are special reasons why case-notes *are* of historical value They are, for instance, the best source for the history of the introduction of the physical examination of patients and of other methods of investigation, of the invention and applications of pathological investigations, such as the chemical testing of urine, of the introduction of bacteriological principles into medical consciousness, and of the development of radio-diagnosis and the introduction of radiotherapy Case-notes also provide a far more accurate basis for the history of treatment than do textbooks, because they tell what was in fact given to patients, and not what was recommended Some historical matters (such as the rise and fall of the use of arsenic in internal medicine) would be impossible to elucidate without original records They also provide first-hand evidence of the changing attitude of doctors to disease at different times, and contain a great deal of intimate detail about habits, food, drink, clothing, housing, and families of patients Case-notes, therefore, constitute a very accurate and impartial record of social history There are thus many sound reasons for their preservation as far as is practicable

It may be physically impossible for the organisation which produces case-notes or other medical records to provide permanent storage for all of them, but every effort should be made to preserve them The use of scarce office space for the storage of these records may be difficult to justify, but the attic, roof space, or cellar, will provide an alternative "limbo" If these records can be kept, in whatever order and state (damp excepted), they will at least exist and still be available for the painstaking searcher who desperately needs them.

By their nature, medical records, especially clinical records, are highly confidential, and before allowing them to leave their possession, practitioners and institutions will certainly wish to be assured that this confidential nature will be respected Certain standard conditions of receipt by archive repositories should attach to accessions of medical records for the protection of all parties In general, no clinical records should be available for public inspection until a hundred years after the date of the last entry This term could be varied at the discretion of the archivist in the case of a person conducting bona-fide research on production of evidence of his standing and competence In no case should names of patients be quoted, and individual cases should not be identified by name in any work published as a result of such research, until after the passage of a hundred years Persons consulting medical records should be required to give a signed undertaking to observe these conditions before being allowed access to the information A general condition of deposit in the case of clinical records or case-books would be that those records would only be opened to members of the public subject to the above restrictions Any lists of the records compiled in the archive repository and placed on open access shelves in search rooms should bear clear statements of these restricted terms of access It is felt that such conditions, if clearly explained to practitioners and institutions before a deposit were made, would satisfy them that the confidential nature of the records would not be abused Any other conditions which individual depositors wish to impose would be respected by repositories, insofar as it would be practicable to do so

---

* Copies of this memorandum can be obtained free from the Secretary, Records Preservation Section, British Records Association, The Charterhouse, London, E C 1

† In the case of the files in which the clinical notes of each hospital patient are nowadays kept, it will almost certainly be necessary to resort to some process of sampling, a matter which is at present under careful consideration

The kind of record ‡ to be searched for will comprise

Foundation deeds, statutes and rules of medical societies and institutions, medical charities and dispensaries, and medical schools

Minute books of governing bodies and committees

Ledgers and main accounting records

Annual reports and balance sheets

Registers, such as those of students undergoing training or of patients admitted to hospital, where more than the patient's name is given

Letters written by medical men which may be of professional or personal interest, (the former may prescribe a course of treatment, give an opinion on a case or throw light on medical education, the latter may have biographical value)

Lecture notes, which may provide the only source of information for lectures of distinguished physicians and surgeons and give some indication of the state of knowledge of the time, and other students' notes

Licences (including letters testimonial) to practise medicine generally or in one of its branches

Partnership agreements

Account books and ledgers, which may contain information about the size of a doctor's practice, professional fees, the cost of drugs, &c

Case books and medical diaries

Prescription books

When the fate of any medical records is being considered, it would be wise to enlist the assistance of the Records Preservation Section of the British Records Association, county or borough archivists, the Royal College of Physicians of London, the Royal College of Surgeons of England, the Wellcome Historical Medical Library, or the National Register of Archives, with a view to arranging for their deposit in a suitable repository In order that medical and social historians, and others, may have ready access to this material, the Royal College of Physicians has agreed to act as a centre of information and advice on what should be kept or what may be found in the various repositories Copies of any lists of deposited records made by local archivists and reproduced by the National Register of Archives will be sent to the Royal College of Physicians, which will also pass on to the National Register of Archives information about the location of records which it receives These reports will, of course, be available to students at the central office of the National Register of Archives in Quality House off Chancery Lane, W C 2, on the same basis as other reports on various types of archives

In England Now

A Running Commentary by Peripatetic Correspondents

THE other week we were discussing new research projects, and as one of our colleagues is interested in the medical aspects of boxing and another in head injuries, an experimental study of boxing pathology was suggested Of course this has been done already, but the older technique of creeping up behind some poor animal and hitting it on the head with a blunt instrument could surely be refined Why not teach apes to box and have them knocked out under conditions of autonomic and endocrine discharge comparable to those of the ring? But someone pointed out that we might run into difficulties. Boxing has been recommended by Professor Whitteridge as a sport eminently suitable for subhuman primates, but the Home Office is likely to disagree and might well refuse to allow such experiments on the grounds that boxing is too cruel a procedure to be used on the animals in relation to the new information likely to be gained And admittedly it could not be contended that the pathological findings would lead to new medical knowledge—that is, unless anyone has seriously suggested that blows to the head are beneficial to the brain

For most husbands sleep is usually firmly on the credit side of the marriage balance-sheet Deep sleep at night, blissful dozing off in the companionship of an evening by the fireside, a brief nap after lunch until the washing-up is finished But for wives it seems to be different Are men really the chief disturbers of the peace, or is it just that the women complain more?

" He sleeps nice enough until two in the morning Then he gets up and goes downstairs If that doesn't wake me, it's the pipes rattling as he fills the kettle at the sink So I lie there, listening to him moving around in the kitchen and wondering what he will be eating this time At three o'clock he's back in bed again and asleep at once, while with me, it's ages before I can get off His mother says his father used to be exactly the same "

" Seems at work he has a machine where he pushes something down with his foot and pulls down a lever with his hand So at night he has to start doing this in his sleep !"

" Well you know what his breathing's like, doctor, and on top of that, cough, cough best part of the night, and if that's not bad enough, he goes and covers his head with the blankets It's that queer and muffled like, I keep thinking he must be suffocating "

" He snores something really dreadful I had to move into our Pat's room with her, but we can still hear him through the wall "

" Well, I made a bad mistake I didn't know when I was well off Ted's all right, good fun to be out with, but he's jumpy, can't never keep still, even in bed Then he's sharp with the kids He smacked our Vera yesterday, right in the middle of Woolworth's, and she gave one scream out, '*I want my dad!*' I could have sunk through the floor Now Nick was dead quiet, a twenty-four-hour-a-day sort of husband, and God help me, he let me sleep "

* * *

A faint reminiscent odour stole on my senses as I sat at the Comitia of the Royal College of Physicians Ripe apples, acetone bodies, there must be a diabetic close at hand, I reflected, and whispered my suspicion to the colleague on my right, hoping he was not the sufferer " Can't say I notice it myself," he replied—a heavy smoker perhaps—" But don't you think it might be the nail varnish of the lady on your left?"

* * *

" In winter time you will probably have to travel quite a lot by dog-sledge, and if you have skis bring them along " I left the Minister's office with a vision in my mind labelled " Doctor to the Great White North " Two weeks ago and well into the G W N I was introduced to my first dog-team The sledge seemed orthodox enough, but there were only three dogs—not the burly huskies of film and book, but a rather apologetic bunch Two were on their feet, one sat down and looked longingly at home I shouted " Mush " in an inquiring sort of way Surely every dog has heard of this word, but not my three Eventually by taking the lead at the traces I got them moving No 3 sat down for quite a while before getting up and trying to run back to the kennel Some yards further on I tired of running behind the sledge and hopped on to the runners The whole outfit stopped abruptly, and some mention was made of the shop steward—at least that is what it sounded like I climbed off, apologised, took the lead trace, and away we went again. I soon took up my old position behind the sledge and it was two minutes before I noticed that the traces were slack behind the dogs and that I was pushing the sledge across the ice. I made a mental note that I had a lot to learn about driving a dog-team and resolved to take skis the next time But it was an unhappy occasion I shot off a snow-bank into the sea and ended my journey complete with skis and some incongruity in the back of a rowing boat. It seems that I have not yet settled the problem of transport

---

‡ Examples of many such records are given in the *Catalogue of an Exhibition of Medical Records* shown in 1958 at the Royal College of Physicians of London (published by the British Records Association, The Charterhouse, E C 1, price 2*s* 6*d*)

* * *

I used to step smartly out of the front door on my eager way to work Now I hesitate on the threshold, cautiously poke my head out, look both ways, and then proceed, only to shy again at the intersection of the garden paths You see, I have acquired a new conditioned reflex. As an industrial medical officer I have found that it is wise to assume that there is a "stacatruc" round every corner and a lorry at every crossing It is bad enough walking or driving across a network of railway lines, but at a steelworks you are liable to bump into very hot pieces of metal as you try to avoid great ingots swinging through the air on unpredictable courses In coal-mines there is usually just time to flatten against the walls when unattended trucks come hurtling along rails that also serve as footpaths

I would like to put this explanation on record before it is assumed that the nerve of a once-intrepid hockey-player has finally gone On second thoughts, perhaps it has

* * *

Our Transatlantic friend is not accustomed to medicine in the Welfare State Imagine her surprise when she attended the antenatal clinic of a London teaching hospital and Sister said "Can you spend a penny, dear?" As yet unfamiliar with the English idiom, she was only struck by the smallness of the sum "Sure I can spend a penny" she replied, "but what for?" Sister explained what was wanted "Oh! Urinalysis Gosh, that's cheap It would cost a dollar fifty back home!"

BALLADE OF ACADEMIC INEPTITUDE

Well, no, I hadn't heard of that before,
(Doubtless it's common knowledge to the rest)
Written, you say, in 1834,
And published by a firm in Budapest?
I try not to admit that I'm impressed.
To me such virtuosity comes hard,
But to achieve it I shall do my best,
I write it down upon a little card.

Eager for knowledge, I read books galore,
Though reading tends to make me more depressed
Since each one read suggests a couple more,
Progression geometric spoils my quest.
In any case, I never could digest
So many facts, some I must disregard,
And others are more use if they're compressed.
I write it down upon a little card

I never shall be a contributor
To learned journals, were I to suggest
A thesis, they would quietly deplore
Such rashness, though I meant it for the best.
It's very hard merely to keep abreast
Of modern trends I'm always on my guard
Lest I should miss something of interest,
I write it down upon a little card.

Envoi

Prince, my despair shall not be manifest.
In spite of all I'll keep up the facade.
No-one shall know how much I am distressed,
I write it down upon a little card.

Letters to the Editor

BRETYLIUM TOSYLATE IN THE TREATMENT OF HYPERTENSION

SIR,—The report on bretylium tosylate by Professor McMichael and his colleagues in last week's *Lancet* will be of much interest to all concerned with the treatment of hypertension As they point out, there has been great need of a drug which patients could tolerate with less difficulty than those which act by ganglion blockade Our experience has been of a similar group of patients treated over a similar period of time, and likewise many had previously been on pentolinium, mecamylamine, or pempidine In our hands, however, the results have been rather less promising, and the difficulties encountered force the conclusion that while bretylium is certainly an early probe into new territory, it has not been demonstrated over a sufficient period of time that it is a satisfactory drug for the routine treatment of hypertensive patients While there is no doubt that many of our patients previously treated with ganglion-blocking drugs have expressed pleasure at being relieved of the unpleasant side-effects which were the inevitable accompaniment of treatment, they have been unaware at this stage that their blood-pressures were still uncontrolled or only partially controlled When serial increases in dosage were necessary or new side-effects began to appear, fewer patients were heard to express satisfaction

We have found it best to begin with 100 mg ($^1/_2$ tablet) three times a day because some patients are very sensitive to the drug It usually takes several weeks or months to determine the optimal dosage

Difficulties in the control of blood-pressure with bretylium can be classified under three headings—tolerance, instability of the blood-pressure, and side-effects

(1) *Tolerance*—A preliminary fall in pressure has been recorded in most cases, but when kept under observation for several months a large proportion of patients (75%) have been found to require a steady increase in the dose in order to maintain control In several resistant cases control has been impossible Patients treated with bretylium must thus continue under the irksome close supervision which has been required to achieve satisfactory control with other drugs

It may be that combination of bretylium with a ganglion-blocking drug, each in relatively smaller dosage, and possibly also combined with chlorothiazide, will prove more effective, and our first attempts in this direction are fairly encouraging

(2) *Instability*—Fluctuations in blood-pressure have led to prolonged difficulty in stabilisation. We have observed considerable swings in pressure when recordings are made at hourly intervals through the day; so single readings in consulting-room or clinic may be very misleading Dizziness and occasional syncope have been alarming alike to patients and their medical attendants So far we have been lucky in avoiding disaster, but we are not surprised to learn that others have been less fortunate The absorption studies reported from the Hammersmith Hospital provide a scientific basis for these clinical findings It may be that with increasing experience our technique of administration will improve, but low and variable absorption and relative lack of warning symptoms still constitute a major problem.

(3) *Side-effects*—It can be said at the outset that these have been less frequent and less severe than with any other effective drug used in the treatment of hypertension over the past ten years

Treatment has had to be abandoned on only two occasions, but, as can be seen from the following figures, the incidence of side-effects is high. Some are of considerable interest and merit discussion.

Side-effects in 40 Patients

Dizziness (not due to postural hypotension)	15	Nasal congestion	6
Chest constriction and paræsthesiæ	9	Headache	6
Parotid pain	9	Weakness	6
Diarrhœa	8	Salivation	3
Frequency	8	Sweating	3
		Dyspnœa	3
		Tinnitus	3

Dizziness may, of course, be due to postural hypotension, but has also been a subjective complaint in many in whom the pressure is still high Since this symptom has not been a feature of treatment with other hypotensive drugs it must presumably be due to bretylium

A sense of *constriction or paræsthesiæ* across the chest and down the arms has been another unexplained complaint which in some ways simulates angina pectoris but bears no relation to effort and is not accompanied by electrocardiographic changes

Possibly both this symptom and dizziness are due to sensory disturbances in the distribution of the cervical and upper dorsal sympathetic nerves

Parotid pain may be severe and recur at the beginning of each meal or from sucking a sweet It is not always associated with excessive salivation

Diarrhœa is seldom troublesome, but in some patients it recurs with every increase in dose

Frequency of micturition has been reported by patients of both sexes and is usually nocturnal Diarrhœa and frequency may perhaps be attributed to a swing from parasympathetic blockade to parasympathetic " release " and sympathetic blockade

Nasal stuffiness tends to persist but has not been disabling

Headache is presumably due to vasodilatation

Weakness is an ill-defined sensation and we have no evidence that it is due to actual muscular paresis

There is some suggestive evidence that dyspnœa may be due to pulmonary œdema

In general, side-effects have been mild, and some of the ill-defined complaints may be due to autonomic imbalance, but further investigation is required for their elucidation

We thought that a useful purpose might be served by grading our results in a similar manner to that described in the paper by Professor McMichael and his colleagues On this basis, as far as experience goes, we have obtained 50% of good results compared with their 60% We have been accustomed, however, to using somewhat different standards for grading results in that a good response has been claimed only if the standing diastolic pressure could be maintained at normal or near normal levels (and not simply a reduction of the diastolic pressure by, say, 20 mm Hg) By these criteria our proportion of satisfactory results with bretylium is lower

Experience to date would therefore seem to indicate, as the Hammersmith workers suggest, that bretylium, for all its advantages, is probably less reliable than the ganglion-blocking drugs at present available, but experience is still limited and it is too early to make a strict comparison

From these observations it is clear that no highroad has opened before the hypertensive patient, and for this reason we feel strongly that a new compound such as this should not be widely recommended before the results of adequate clinical trials have been published, on a basis of which all clinicians can draw their own conclusions To do so is to invite difficulty, disappointment, and even disaster, since patients who are inadequately controlled may sustain severe postural hypotension and may even lose their lives from syncope, cerebrovascular accident, or myocardial infarction Without preliminary hospital assessment some will receive unnecessary treatment and others with serious hypertensive disease will receive inadequate treatment If patients living at a distance are discharged from hospital, it is far better that treatment should be continued under the supervision of a clinic or a physician thoroughly familiar with all aspects and difficulties of the treatment of hypertension, and where this is not possible it is better not to use relatively untried remedies

Those who intend to use such drugs should be aware of the difficulties, dangers, and possible side-effects, and these facts should be stressed in all recommendations for treatment and in particular by the advertisers

We have no doubt that after 10 years of ganglion-blocking drugs a new era is beginning in the treatment of hypertension, and doubtless this is one of the first of a new series of very promising preparations Its chemical, pharmacological, hæmodynamic, and therapeutic effects are of very great interest and importance, and much credit is due to the research-workers responsible for its production, but it would be a profound mistake to imagine that the treatment of hypertension has been greatly simplified In a way it has become more complex, because now new possibilities exist and the relatively experienced physician may be tempted to dabble with mild cases or persist too long in resistant severe cases Before these drugs are widely used in practice far more experience should accumulate

RICHARD TURNER
Edinburgh CLIFTON LOWTHER

THE MARRIED MENTAL DEFECTIVE

SIR,—The follow-up study of married mental defectives in Sheffield, outlined by Dr Shaw and Dr Wright (Jan 30), is most interesting, but disturbing

Of the original 242 defectives, 45 are untraced, the majority of the remainder show an I Q distribution of between 50 and 69, a much higher birth-rate, infant-mortality rate, unemployment-rate, criminal record, and percentage of their children attending special schools than applies to the community at large

Live births were 50% greater than the norm for women married at the same age and for the same length of time, infant-mortality rates, such as are known, were very much greater than for the community at large (26 infants known to have died), a third of the families with one or more children were known to the National Society for the Prevention of Cruelty to Children or under the care of the children's department, and the percentage of their children at special schools seventeen times higher than for the Sheffield school population as a whole

Surely this *is* a clear-cut picture which demands some action other than the patience and forbearance and tolerance that the authors ask of other people in the same community ? It is good to know that some of the defectives are leading normal lives Are the others offered birth-control advice, or indeed sterilisation and, if not, why not ?

The laws relating to sterilisation in this country are obscure, but most people agree that the subnormal couples with a large family and incapable of dealing with birth-control measures are eligible, if capable of giving consent, as also are those with subnormal mentality with a known eugenic chance of inheritance A high proportion of these families would seem to come into one or other of these categories Surely, if they are considered capable of making decisions to get married and have children, they must equally be capable of taking decisions about sterilisation ?

Compulsory eugenic sterilisation is, of course, not legal, but I find it difficult to believe that some, at least, of such couples, faced with the difficulties that this survey brings to light, would be unwilling to accept birth-control advice or sterilisation, if offered it

London, N W 1 ELEANOR MEARS

PERTHES' DISEASE

SIR,—Your annotation last week on Perthes' disease is welcome, for it may call the attention of the medical profession beyond the restricted field of orthopædic surgeons towards this condition Nevertheless, it does not mention a factor which may be of decisive importance in its ætiology—namely, that with individual and very probably racial variations, from the age of three to eight years the blood-supply of the proximal femoral epiphysis comes through the small group of lateral epiphyseal vessels without complementary supply from the round ligament or the metaphyseal vessels This precarious system of blood-flow occurs, at least in the white child, until or before the age of eight years, while the children of African origin seem to preserve the fœtel circulation through the vessels of the ligamentum teres throughout childhood Perhaps for this reason the Negro child appears to be immune to Perthes', or at least seems to be only exceptionally affected by it as compared with the European child

As to the late consequences of Perthes' disease, in our analysis of over 125 cases we found that, as was to be expected, the only hips suffering from osteoarthritis in adulthood were those left by the early osteochondritis either misshaped or incongruent, or both Thus, to prevent this possible calamity all precautions should be taken, among them, for the moment, bed recumbency during the period when the dead bone is replaced by soft, malleable new cartilage

Nuffield Orthopædic Centre, Oxford J TRUETA

CONTROL OF ANTICOAGULANT THERAPY

SIR,—The isolated sentence from our paper quoted by Professor Quick (Jan. 30) was meant in no way to detract from the basic physiological and practical diagnostic merits of the one-stage prothrombin-time technique Still less could the sentence be construed as having any relevance to very different procedures like the thromboplastin generation test, the reasons for this cannot be given here, and no-one is more aware of them than Professor Quick. Indeed, the offending sentence has little meaning at all except within the context of anticoagulant therapy, which was the subject of our discussion

The acknowledged virtues of Professor Quick's test, described by us as a landmark in the physiology of coagulation, are too great to be seriously impugned by the recognition of certain limitations within a given context We specified and discussed the shortcomings we had in mind they refer only to the use of the unmodified test in the routine control of anticoagulant therapy and are not mentioned in Professor Quick's letter, while he appears to rebuke us for criticisms we did not make Surely he would not deny that unduly severe depression of true prothrombin and of factor IX can exist unrevealed by the one-stage test, and that bleeding does occur, though not often, when the clotting-time is within the therapeutic range With plasma from patients under coumarin treatment (though more doubtfully in the case of isolated deficiencies) thrombotest is sensitive to variations in all four factors concerned. Unlike the one-stage test it has been tailored to meet the requirements of anticoagulant control, successfully so far as we can judge though more extended trial should settle this question

One at least of Professor Quick's shafts—the glass-lined blood-vessels—was misfired, whether through misreading on his part or obscure writing on ours We did not list insensitivity to the contact factor as a shortcoming of the Quick test, but sensitivity to it as a disadvantage of thrombotest

Dr Laurie is quite right in his statement (Jan 23) of a much higher price for commercially supplied thrombotest reagent than the *4d* per test suggested in our paper (Dec 26) This over-modest figure was innocently based on the value given for Customs purposes added to the duty charged—amounting in fact to *3½d* per test We have since confirmed that the present cost per test of purchased reagent would be about *1s 6d* , a price at which thrombotest, with all its technical virtues, would be unjustifiably dear for routine use in this country It is doubtful whether any test costing more than *6d* for the reagent is worth while A way of reducing the cost of thrombotest may be found—e g , by using smaller volumes of blood and reagent, though so far our own experience with small volumes is not encouraging

THE SIGN OF BABINSKI

SIR,—In your leading article last week, reviewing the history and significance of this sign—of which Walshe has written[1] that "there is perhaps no more important physical sign in clinical neurology"—you fail to mention the curious but surely relevant fact that the Babinski reflex can be demonstrated in many hypnotic subjects when regressed to infancy This is difficult to explain on the information available, unless there were some evidence of concurrent neurological or biochemical changes as a result of regression or the hypnotic trance itself But there is to date no such evidence

This phenomenon was investigated in America by Gidro-Frank and Buch,[2] who found that the change of response from plantar to extensor was accompanied by what they described as a reversal of the flexor-extensor chronaxie ratio, which, it was claimed, is normally the case in the truly infantile condition Later True and Stephenson [3] confirmed the presence of this reflex in subjects regressed to infancy, but showed that the E E G was nevertheless of the adult form However, the genuineness of the phenomenon is still debated on both sides of the Atlantic and is, indeed, very difficult to prove, although most deep-trance hypnotic subjects will produce the response Gidro-Frank and Buch claimed that their subjects had no knowledge of the reflex or the intention of the investigators, but for my part I have not yet discovered a suitable subject of whom it could be said with certainty that there was no such knowledge But one subject, a student nurse in her first year, when deliberately misinformed and told with authority (as a temporary, experimental measure) that she had got it muddled and that the infantile response was flexor, nevertheless provided a first-class demonstration of the extensor reaction when regressed to the age of five months

Lower Beeding,
Horsham, Sussex

STEPHEN BLACK

SIR,—Your interesting editorial mentions instances of a temporary Babinski sign, rapidly reverting to normal A more gradual reversion can also occur in cerebral vascular disease

Examples of this were seen when 125 patients with hemiplegia, following cerebral vascular accident, were examined at fortnightly intervals for six months Some 53 of these cases showed an up-going toe on both sides the remaining 72 had a positive sign on one side only Out of these 178 responses, no less than 41 (25%) had returned to normal within six months Such reversion took less than two months in 8 patients, from two to four months in 14 patients, and more than four months in 17 patients 1 patient with bilateral Babinski signs showed reversion in one week on the left side and three months on the right side

CASE-FATALITY IN TEACHING AND NON-TEACHING HOSPITALS

SIR,—We should like to amplify the last paragraph of Mr Ellison Nash's letter of Jan 23.

No doubt in the larger non-teaching hospitals all the night emergency anæsthetics are administered by junior staff, but this is not the case in many smaller hospitals. Most provincial hospitals of 300-400 beds have establishment for only one resident anæsthetist—if they can find one. On his nights off duty, usually six out of each fourteen, and for the first few months of each new appointment, every night anæsthetic is administered by a consultant.

In one such hospital of 300 beds, in 1958 the resident anæsthetist gave 342 anæsthetics for emergencies of all kinds, and the consultants, with 16 nominal sessions, gave or personally supervised 322 Some of these were when the consultants concerned were already in the hospital; considerably more than half entailed special visits outside their normal hospital hours.

These figures are not exceptional, but probably represent the average for such hospitals

The quality of work must surely deteriorate under such conditions, where the individual is frequently tired before the start of a fresh routine day, whatever his actual status With advancing years recovery from a night's work is apt to be slower and less complete

EFFECT OF BEER ON BLOOD FIBRINOLYTIC ACTIVITY

SIR,—Dr Ingram (Feb. 6) cannot have read our paper very carefully We did not, as he suggests, compare the effect of a large volume (10–40 oz) of an alcoholic drink with that of a small volume (2 oz) on blood fibrinolytic activity It is stated both in the text and in the heading of table III that the 2 oz. of whisky were taken in a pint of water. A separate statement to this effect is not made about the results quoted in table I, and I think that it should have been, but this hardly justifies Dr Ingram's sweeping misquotation

Since he asks whether the lysis-time is prolonged by swallowing 10–40 oz of water, I can tell him from other experiments that it is not

AUTOTRANSFUSION IN RUPTURED ECTOPIC GESTATION

SIR,—Professor Chassar Moir in his letter of Jan 2 is the only contributor to the correspondence following Mr Aziz's letter (Dec 12) who has mentioned the age of the blood from the peritoneal cavity, and he was not precise

Hamilton Bailey's *Emergency Surgery* counsels hesitation when the hæmorrhage is more than 10 hours old, and an earlier edition I believe gave 8 hours as a definite contraindication

In my experience in West Africa cases almost never presented as early as this, and in the several dozen cases I had to treat I never attempted autotransfusion In this course I was influenced by Hamilton Bailey, and by experience and teaching on first arrival abroad, because these cases did so well with immediate laparotomy alone, reviving almost dramatically from the time the bleeding point was clamped One gained the impression that if they had a pulse when they had been anæsthetised and reached the table, they would survive

I am not decrying the practice of transfusing freshly shed blood, but it seems an important point to know how late it may safely be used, for the guidance of those whose work lies in those areas where the average time before a ruptured ectopic is seen is probably well over 12 hours. I have often wondered whether the use of blood too long shed has not contributed to an unsuccessful result, the advice to autotransfuse having been followed as long as the blood was fluid

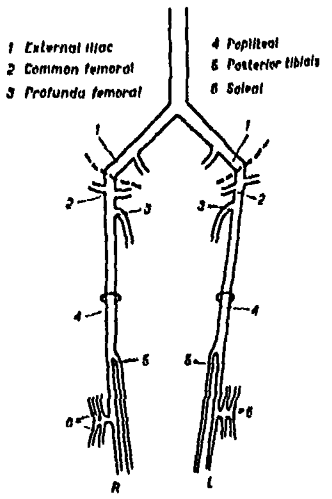
London, N W 1 H. DE GLANVILLE

ÆTIOLOGY AND PATHOGENESIS OF DEEP VEIN THROMBOSIS

SIR,—In his letter of Jan 16, Professor Quick states that *impaired circulation* is rarely, if ever, the primary cause of intravascular clotting and postulates that deep vein thrombosis is initiated by *local injury* of a vessel wall I take the opposite view, that a reduced venous flow is essential and that local injury is rarely the cause. Of course, he states that the secondary added thrombosis is dependent on the locally formed thrombin not being swept away by a normal venous flow and thus slowing of the venous stream would explain propagation of thrombi.

Local trauma cannot explain venous thrombosis in patients without injury (medical cases) or in those with injury away from the lower limbs; nor the multiple and varied distribution of the thrombi found at necropsy. Routine dissection of the deep veins of the whole lower venous tree in patients dying after various injuries has shown that venous thrombosis is very common, that the frequency is related to advancing age and survival period (bed rest), that the nature of injury has little direct influence; and that a large variety of patterns of thrombosis occurs.[1] [2]

These patterns indicate that thrombosis *begins* at one or more *of several independent sites* *Six main primary sites are recognised (see accompanying figure)* (1) the iliac vein, generally the external iliac vein just above the inguinal ligament, (2) the common femoral vein including the mouths of the medial and lateral circumflex veins, (3) the termination of the deep femoral vein, usually at a valve cusp guarding the ostium; (4) the popliteal vein near the adductor ring, (5) the posterior tibial vein, and (6) the intramuscular veins of the calf, particularly the soleal veins *Thrombosis at one site is independent of thrombosis elsewhere* and may then extend by forward propagation or retrogradely after occlusion of the lumen. Only in this way can the various patterns of thrombosis found be explained



The frequency and extent of thrombosis are not related to the site of injury Thrombosis is common (50–80%) even in patients dying after injuries away from the lower limbs provided that they survive longer than 4–7 days and are older than 45–50 years Moreover, thrombosis is generally bilateral even in patients with injury confined to one limb

---

[1] Sevitt, S in Modern Trends in Accident Surgery and Medicine (edited by R Clarke, F G Badger, and S Sevitt), p 247 London, 1959

[2] Sevitt, S, Gallagher, N G (in the press)

The multiplicity of primary foci and the lack of relationship of thrombosis to the site or side of injury cannot be explained by local trauma, and this is supported by histological observations which show that recent thrombi are laid down on normal endothelium

That advancing age and duration of bed rest (survival period) are the most important factors predisposing to thrombosis supports the old contention that venous stasis plays a major ætiological role This is also supported by abundant evidence that the blood-flow through the lower limbs is greatly slowed during bed rest.

Emptying of veins depends on muscle contraction, and lack of this, particularly in the elderly put to bed for any reason, will allow the blood in the lower limbs to become stagnant. Thus, anatomy and the dynamics of blood-flow decide where thrombi *begin* to form. Thrombosis occurs in the soleal veins because they become distended with stagnant blood in the horizontal position of bed rest and, as shown by Gibbs[3], because they form a number of inverted intramuscular arcades which increase in number and lumen diameter with advancing age Thrombosis of the posterior tibial veins is possibly encouraged by the relationship of the vein to the upper edge of the soleus muscle, whilst the deep intramuscular location of the profunda femoris vein and pressure from the overlying adductor muscles help to slow its venous stream. Further, the inguinal ligament facilitates thrombosis in the common femoral vein because it may compress the vein when the thigh is flexed on the trunk, as in Fowler's position Eddying of the stagnant blood-flow with consequent local silting of platelets and leucocytes on to endothelium probably plays a part in initiating thrombosis at least in the thigh and pelvic veins Eddying and silting is likely to occur at valves and mouths of vein junctions at the termination of the profunda femoris, medial and lateral circumflex veins, and other tributaries of the common femoral vein Above the inguinal ligament eddying and silting may initiate thrombosis in the external iliac vein because, when the body is horizontal, there is an acute weir-like change in direction of the slowed column of blood In short, the common denominator of venous thrombosis is venous stasis, and, in addition to venous anatomy, which determines eddying, silting, and primary location of thrombi, the major roles are played by age, immobility, and above all bed rest Injury per se rarely, if ever, plays an ætiological role

Birmingham Accident Hospital S SEVITT

BREECH PRESENTATION AND DELIVERY

SIR,—It would be a pity if external version were not to be attempted The breech presentation is uncomfortable for the patient, and rightly or wrongly the expectant mother is nearly always apprehensive about it Before anyone attempts version, however, he or she must clearly understand that there are two kinds of breech, " a cylinder within a cylinder, and a sphere within a sphere " The former will not turn and can only very rarely be turned, the latter will probably turn themselves (but not certainly) They can, however, be turned, so why not? Vigorous attempts to turn the first type in the antenatal clinic are to be condemned and attempts under anæsthesia should certainly be abolished Anyone who has had a disaster with version and has proved himself "accident-prone" should give it up

The only exceptions I make are (1) if a woman is to be induced under anæsthesia then I would try a version first, (2) occasionally conditions are encountered which would be suitable if the patient could cooperate, but she won't

What is much more serious is the steadily increasing cæsarean-section rate in one hospital over half of the breeches were section in one year By surgical induction the size of the baby can be controlled In this way dystocia will be avoided, and we must all admit that dystocia in the breech is more troublesome than in the cephalic presentation By a wider use of surgical induction, the rate of cæsarean section with all its potential dangers can be kept within responsible limits

London, W 1 C K VARTAN

THE ABNORMAL APPENDIX

SIR,—May I criticise Mr Jewers' reasons (Dec 26) for preferring a paramedian incision?

Firstly I disagree about the ease of approaching the appendix, especially the retrocæcal variety in most cases the appendix can be removed easily through a gridiron incision If the skin incision is made obliquely transverse in a natural skin crease following Langer's lines the incision can readily be extended laterally or medially In dealing with a retrocæcal appendix, which more often lies towards the outer side of the ascending colon, I make my incision rather higher than usual and of adequate length, and have rarely found it necessary to use retractors, provided a good anæsthetic is given, which is most important. On the other hand, removing a similarly positioned appendix via a paramedian incision has always appeared difficult to me Even when the tip of the appendix is lying towards the midline the base may still be found well out in the right iliac fossa and appendicectomy is still carried out more easily by the more direct approach of a gridiron incision

Secondly, I consider the routine use of a paramedian incision, in case one's diagnosis is wrong, is to be deprecated, as it must encourage an attitude of mind whereby any case of abdominal pain is subjected to an exploratory laparotomy I know it is often said that it is far better to take out a normal appendix than to miss a pathological one, but I have a feeling that too many patients are subjected to a laparotomy for abdominal pain and a normal appendix removed to justify this procedure. Even though the risk to life is minimal, it is never non-existent, and in addition to the risk of an anæsthetic death, there is that of intestinal obstruction at a later date from adhesions, and this is greater after a paramedian incision than after a gridiron.

It is preferable to observe the patient for a time if the indication for operation is not clear rather than submit a person to a rushed operation, for it will often be found to be unnecessary In a series of 324 patients admitted to hospital as emergencies with abdominal pain and mostly seen by me, operation was performed for acute appendicitis in 158, conservative treatment for acute appendicitis was instituted in 21, and 59 cases of abdominal pain in which no accurate diagnosis was made initially were observed In many of this last group no final diagnosis was reached There were no deaths in any of these groups Thus, a fairly high proportion of patients admitted as acute abdominal emergencies are found to have very little wrong with them, this applying particularly to the younger female group

Conversely, as Mr Jewers has pointed out, the symptoms and signs in the elderly are singularly lacking, but early diagnosis and operation is as imperative as in the very young I have operated on a number of people over 75, including a few in the 80s, and have found that localisation of the infection is remarkably poor, especially in the obese Severe peritonitis may be present with a normal pulse and temperature and only minimal signs in the abdomen, but invariably there is localised tenderness, however slight, over the appendix. In fact, I would go so far as to say that in any case of suspected acute appendicitis unless this tenderness is present I would question the diagnosis Occasionally, of course, one is sure of some intra-abdominal mischief, but the exact diagnosis is obscure, and in these cases I quite agree with the use of a paramedian incision, but as a rule the commonest conditions with which acute appendicitis may be confused lie in the lower abdomen, and these can be dealt with efficiently by extending the gridiron incision medially and dividing the right rectus muscle transversely The wound heals quickly and soundly

Lastly, citing a low incidence of hernia after a paramedian incision as an argument for adopting this approach is surely contrary to general opinion An incisional hernia after such an incision is not infrequent, whereas I have seen a similar hernia after a gridiron incision once only Regrettably, this was one of my own cases, but the patient was obese, and developed a severe wound infection Fortunately, the repair of this was easy But perhaps the fact that there is a greater incidence of right inguinal hernia in those having had an appendicectomy is what is implied

---

[3] Gibbs, N M *Brit J Surg* 1951, 45, 209

Let me say that I found much of Mr Jewers' paper excellent—and in particular the remarks on the use of antibiotics were most relevant Too often a course of these drugs is started immediately appendicitis comes to mind, even when the infection is mild or non-existent In the late case treated conservatively a long course of antibiotics is not without danger

I remember well a man who had been ill for three weeks before admission being given prolonged chemotherapy, and at operation several months later I removed his appendix and drained a chronic encysted pelvic abscess Postoperative obstruction developed, requiring further operation, from which he subsequently died

My findings regarding the position of the appendix also confirm what Mr Jewers says The figure usually quoted of 0 5% [1] [2] for the retro-ileal position has always seemed too low, while that of 21% [2] or 32% [1] for the pelvic appendix too high Although I have not exact figures available, I have the impression that in my experience the retro-ileal occurs in 5% of cases at least Probably the percentage of pelvic appendices mentioned is elevated by including many cases of subcæcal ones I would not class an appendix as of the pelvic variety unless a part of it is definitely hanging over the pelvic brim On the other hand, I would consider the high retrocæcal appendix due to a maldescended cæcum comparatively rare, whereas that with the cæcum in a relatively normal position is common, the tip of the appendix being found at varying heights behind the ascending colon to as far as the hepatic flexure These usually require removal by the retrograde method, since they are buried in the retrocolic tissues

Grove Park Hospital,
London, S E 12

R F BOLAM

TREATMENT OF INFECTIONS IN HOSPITAL

SIR,—Your annotation of Jan 16 discussed the report of Finland et al on the changing pattern of infections Once again the seriousness of staphylococcal infections was demonstrated

That the old enemy, the hæmolytic streptococcus, is not yet beaten has been suggested by the rather disturbing increase in the isolation of this organism from the throats of children in this area Not only has there been an epidemic of β-hæmolytic streptococcal throat infection in a large school, but also this organism has been isolated from more than a quarter of the throat swabs taken in one children's ward during the past year

During the same period, the number of cases of acute rheumatism and acute glomerulonephritis seemed to be on the increase, so an analysis of the number of medical (as opposed to surgical) patients admitted to three children's wards during the past five years has been made Practically all sick children from this part of the Black Country are admitted to one of these three units All were fresh cases, and subsequent admissions for the same disease have been excluded

Year	*Total admissions*	*Acute rheumatism*	*Acute nephritis*
1955	945	8 (*0 85%*)	11 (*1 16%*)
1956	1014	14 (*1 38%*)	12 (*1 18%*)
1957	1054	5 (*0 47%*)	11 (*1 04%*)
1958	1095	6 (*0 55%*)	6 (*0 55%*)
1959	1169	38 (*3 26%*)	20 (*1 7%*)

From these figures it will be seen that there has been a striking increase in the admission of patients with acute rheumatism and a definite, but less remarkable, rise in the number of children suffering from acute glomerulonephritis One wonders whether this increase in the number of streptococcal infections is widespread If so, is it because penicillin is less frequently used for throat infections at the present time? The broad-spectrum antibiotics which are so often prescribed at present are known to be less effective than penicillin against the streptococcus Or can the commonly occurring penicillin-resistant *Staphylococcus aureus*, concomitantly present, produce enough penicillinase to render the streptococcus less sensitive to penicillin?

Wolverhampton

H EVERLEY JONES

THE COST OF DRUG TREATMENT

SIR,—Recent letters on this subject have made me break a resolution formed some time ago not to send another communication to the Press My present breach is in spite of a conviction that any letter on the subject is only " a voice crying in the wilderness ", but this letter is chiefly to endorse Sir Max Page's remark (Jan 30) that " Savings on drug expenditure leave more money for hospital building, more doctors and more pay for them "

The subject has interested me more particularly since, as adviser on venereal diseases to the Ministry of Health, when, in 1920, I wanted to find money not then available for improvements in the V D service, I began to examine in detail the expenditure of the clinics, hoping that by checking waste the money already being expended could be used to better purpose My investigation revealed waste, sometimes of the most idiotic kind, and prompted economies, *by persuasion*, that resulted in very substantial saving in the cost of the service The experience during the decade 1920–30 convinced me that the average doctor does not give a thought to the question " is this drug in this form and this amount necessary? "

I described the methods by which economies were effected first in 1923 in an article entitled Economy in Drugs and Dressings, which was contributed, by invitation of Dr F N K (later Sir Frederick) Menzies, to the 5th annual report of the Order of St John and the British Red Cross Society on the Voluntary Hospitals in Great Britain, and next in 1951 in a letter to *The Spectator* (Jan 19, p 79) to support an article by Dr M E Lampard, published a fortnight previously in the same periodical, under the title Doctors and Drugs, in which he exclaimed at the waste that was then prevalent I ended that letter with the following remarks " If anyone reading Dr Lampard's article and this letter is tempted to embark on economies in his branch of the N H S, he should not expect thanks I should like to meet anyone who has been thanked for saving public money "

I learnt the importance of economy in drugs quite early in life, being a son of a practitioner who dispensed his own prescriptions Later, as assistant to a country practitioner, I put my knowledge to some use in frequent gentle reproofs of my boss for the cost of his mixtures Still later, in India, when one of my duties was charge of a cantonment hospital, for native civilians, I had to work to a budget which did not err on the side of extravagance and I had to find the money for new instruments, such as cataract knives, by watching every anna It was a very useful experience and it prompts me to suggest that *if* doctors had to work to budgets in respect of drugs, dressings, and instruments—budgets *framed by people with practical experience*—we should see the taxpayers' money used to better purpose in that branch than at present I know because I have tried it and it has worked Often in my visits to V D clinics I was asked by a medical officer if he could have such and such a rather expensive instrument or apparatus, and from information as to the details of his expenditure in his clinic, read in the light of my experience in my own clinic, I was able to tell him how to save enough to buy the tool he wanted

[2] Bailey, H, Love, M A Short Practice of Surgery, p 587 London, 1959

London, S W 1 L W HARRISON

SIR,—Dr Miller and Dr Smith (Jan 2) make the retail pharmacist the scapegoat for the rising drug bill As a retail pharmacist and one-time hospital chief pharmacist, may I reply to the criticism of excessive distributive costs which suggests that retail pharmacists are overpaid for their services

The argument rests on the disparity between the basic cost of drugs and the final cost which is determined by the profit or fee paid to the pharmacist. There is, however, no logical connection between the basic cost and fees paid for distribution Phenobarbitone is cheap, but why should the pharmacist's fee be related to the cost of phenobarbitone ? The cost of the general medical practitioner's share in the distribution of phenobarbitone is at least equal to that of the pharmacist, but no-one would suggest that medical fees should be assessed in this way The pharmacist's fee is related to the cost of providing centres for distribution of drugs as well as for the actual dispensing services In relation to the actual costs of providing the service, the pharmacist is not overpaid—even if the cost of distribution is one-third of the drug bill Not many pharmacists earn more than £1000 per annum from dispensing

The comparison with hospital costs is most misleading—it is very difficult in hospital costing to relate costs to any unit of work The hospital pharmacist makes many economies for the management committee by judicious buying, but comparative costs would have to include a proportion of maintenance that your contributors ignore

It is not generally recognised what a good service the patient gets from the retail pharmacist, who daily has to obtain quickly new proprietaries and who cannot substitute chemical " equivalents " as is done in the hospitals It is, of course, quite true that a more rational distribution of drugs and of medical services could be devised, but costs would still have to be related to many other factors apart from basic prices of drugs

London, E C 1 W C KING

SKIN CHANGES IN HYPOCALCÆMIA

SIR,—The paper by Professor Dent and Dr Garretts (Jan 16) leads me to record a further case confirming their findings, but I also wish to point out that the presenting feature in this patient was his mental state

A 64-year-old man was recently admitted to hospital suffering from quite severe depression, retardation, and lack of initiative He had widespread scaling of the skin, especially on the arms . There was bluish-red erythema in the folds of the groins with some oozing He had generalised muscular hypotonia and passed bulky stools The following tests were carried out

Blood-picture showed anæmia with some macrocytosis

Glucose-tolerance test showed sugar levels of 86, 81, 111, 113, and 106 mg per 100 ml at half-hourly intervals No glycosuria

Serum-protein 6 1 g (albumin 3 8 g , globulin 2 3 g) per 100 ml Serum-calcium 6 7 mg , phosphorus 3 0 mg , bilirubin (direct negative) 0 5 mg , thymol turbidity 2 units, zinc turbidity 5 units, alkaline-phosphatase 30 King-Armstrong units per 100 ml

Faeces 72-hours total fat 108 g (80% total solids), split fat 93 g (68% total fat)

Almost certainly a case of idiopathic steatorrhœa, he is being treated, with improvement, by folic acid, ' Parentrovite ', and imipramine.

The skin lesions have been recurrent for sixteen years His psychiatric history reveals that he had electroconvulsion therapy for depression in two other hospitals in 1952 and 1954 He was a patient here in 1955 and last year, on both occasions in a state of hypomania In 1955 his serum-calcium was 9 5 mg per 100 ml , and there was only slight scaling of the arms

Thus his " skin health " seems associated with his blood-calcium level An episode of depression accompanied the hypocalcæmia, and as 2 of Professor Dent and Dr Garretts' 4 cases showed states of acute anxiety and suicide-level depression, I think it is essential to emphasise the dangers, from a psychiatric point of view, in this condition

I wish to thank Dr J A S Mulligan for permission to publish this case

St. Luke s Hospital,
Armagh
W A GORDON MACCALLUM

SIR,—We are interested to note the point raised last week by Dr Brian Russell, whose patient with erythrodermia did not show a correlation between the rash and the hypocalcæmia We are not surprised about this as we intended to state in our paper that it is only in certain patients that such a correlation can be noted The vast majority of patients with hypocalcæmia do not get any sort of skin trouble, and the majority with various forms of skin trouble do not have hypocalcæmia The point of our paper was only to state that sometimes there was such a correlation between hypocalcæmia and skin disease and that in such cases it was important to deal with it as there was no other treatment We are sorry if it was not clear enough in our paper

University College Hospital Medical
School, London, W C 1
C E DENT
M GARRETTS

INFANTILE STRUCTURAL SCOLIOSIS

SIR,—Your annotation of Jan 30 is a curious one It says " there is much to be gained by the further study of the natural history of severe deformities, and until this is understood it is wrong to claim that any particular treatment has been successful " I would find this easier to understand if I knew what methods and what claims were being referred to I do not appear in the list of references, but as far as I know I am the only surgeon to suggest[1] that the terrible deformity of " idiopathic scoliosis " starts in utero, and can be detected in early infancy and cured at that stage by splinting and physiotherapy The present teaching of orthopædic surgeons appears to be that because some cases get better spontaneously therefore none at all should be treated

I do not know what they would reply to the mother of a child with " severe and progressive scoliosis " who says, as several have said to me, " I kept telling them that the baby's spine was crooked, and they just laughed at me "

I have aroused considerable resentment by suggesting that treatment is absent because there is no classical splint to reverse the curve of the spine, any more than there is one to reverse the commonest of all elements in deformities of the feet—that of equinus

London, W 1 DENIS BROWNE

*** The prime object of our leaders and annotations is to note and discuss new work we hardly ever aim at a comprehensive review and an exhaustive list of references In this annotation we were concerned with the recently published work of James et al and not with all the possible ætiological factors that might combine to produce the condition We thus excuse ourselves for feeling no need to recall Mr Denis Browne's considerable and well-known contributions to this subject We still affirm that the best treatment is usually based on a knowledge of what causes natural resolution It was never our intention to suggest that *no* deformities should be treated —Ed L

ANTI-SMOKING CAMPAIGN

Sir,—The article last week on the efficacy of an anti-smoking campaign is full of interest It is not surprising that it failed to diminish the amount of smoking, because " drug addicts " cannot be cured by exhortation, the only remedy is to make a harmless cigarette that people will smoke

It is interesting that after the campaign there was evidence that people realised to a greater extent the harm done to bronchitic people, but it did *not* increase the awareness of the connection between smoking and cancer of the lung The authors are undoubtedly correct in saying that this is a form of " emotional blockage " due to fear of cancer " long nurtured by a conspiracy of silence " This psychological problem can best be solved by personal conversations between a lay person and a member of the nursing profession—i e , health visitors, district nurses, and midwives If local authorities would spend half the time, money, and energy at present spent on anti-smoking campaigns in arranging for their nurses to talk to the public about the symptoms of the " accessible cancers " they would get immediate results

Oxford MALCOLM DONALDSON

CASUALTIES AND CASUALS

Sir,—Two points may influence Dr Fry's conclusions (Jan 16) and Dr Doyne Bell's comments upon them (Jan 30)

Both doctors are Londoners London has a large " floating population " which increases the number of " casuals "—travellers, troupers, workmen on location, and so on They have no family doctor near them because they have no family life They have a right, one might think, to look to the nearest hospital when they are in need All casualty departments have a few of these patients, but London has a lot

Secondly, the little clinics doing family doctor's work which have developed in casualty departments grow by what they feed on The more they are treated, the more they come Dr Fry seems to disapprove of them, and so do I Nevertheless, if I remember rightly many young casualty officers did not discourage these opportunities to try their wings, from the shelter of their hospitals, before launching out upon more serious flights If the hospitals themselves disapprove nowadays, I do not think they did so always

My first point is that this work should not entirely disappear, and my second that to a very large extent the volume of it depends upon what you make it A consistent policy about what one's own casualty department considers it should treat, and what can be treated *equally well or better in the doctor's* surgery, can of itself determine in which way the work develops I have misgivings about national decisions about what casualty departments as a whole should or should not do

Dr Doyne Bell refers to the " consultant who is ultimately responsible " and to the difficulty of deciding which particular specialist would be the most appropriate I often wonder what this ultimate responsibility means, and suspect its interpretation in many minds would be " carrying the can " Strict conformity with the limits each specialty sets for itself could reduce casualty department work to a farce, and I detect signs that the farce is likely to begin before long The casualty department cuts across all specialties Because it is very often concerned in emergencies and accidents *of all types* it would be a great mistake for it to be gathered into any particular sphere of specialist influence In most hospitals, on the other hand, staffing problems make it impossible to share the work amongst all the different specialties concerned. The sooner we accept that the casualty department is part of the hospital as a whole, and that it should command the support of all the faculties, the better for the hospital service

As a surgeon, I should like to agree with Dr Doyne Bell that our casualty departments could be defined as accident, emergency, and dressing stations I do agree that we could make many of them much more like his definition than they are As a doctor, I see quite a number of cases outside his definition that I simply cannot send away

Sunderland T G LOWDEN

NATURAL HISTORY OF CAVERNOUS HAEMANGIOMATA

Sir,—

> " In Xanadu did Kubla Khan
> A stately pleasure dome decree
> Where Alph, the sacred river, ran
> Through caverns measureless to man
> Down to a sunless sea "

According to the correspondence in your columns cavernous hæmangiomata appear to be measureless to man's judgment, but I believe the main body of opinion in the many letters gives the truth of the matter So I would have left it, but I have been invoked as an authority and I am convinced that spontaneous resolution, usually in the first decade, is the rule, and I can recall seeing only three adults with lesions of this type However, the obvious lesions, especially those on the face, cause much distress to the parents, and it is usually possible to hasten natural resolution by X-ray dosage well within the safety margin

When parents wish for something to be done I prefer to use X-rays with a half-layer value of 1 mm , or not exceeding 1 5 mm., of aluminium with a dosage of 250r, repeated after a month's interval for three doses Smaller lesions can sometimes be given 300r, and exceptionally four doses might be given. Within this range no erythematous reactions were observed nor any atrophic sequelæ No irradiation was given in the vicinity of the thyroid glands For many years treatment was not given to lesions which were hidden by clothing, and those all disappeared satisfactorily well within the first decade

London, W 1 REGINALD T BRAIN

Sir,—I read Dr Simpson's excellent article (Dec 12) with great interest and I am in full agreement with all the supporters of the " wait and watch " school My only excuse for this letter is to quote from the writings of an acute clinical observer of the pre-X-ray and pre-carbon-dioxide-snow era—Thomas Bateman In the 6th edition of his book, *A Practical Synopsis of Cutaneous Diseases*, according to the arrangement of Dr Willan, published in 1824, on p 331 he writes of this group of nævi

> " Some of these excrescences are raised upon a neck or pedicle, *while some are sessile upon a broad base* Some of them again, although vivid for some time after birth, gradually fade and disappear some remain stationary through life, but commonly vary in intensity of colour at *different seasons* and under circumstances easily explained and others begin to grow and extend, sometimes immediately after birth, and sometimes from incidental causes at a subsequent period, and *from small beginnings* become large and formidable bloody tumours, readily bursting, and pouring out impetuous and alarming hæmorrhages, which, if they do not prove suddenly *fatal*, materially *injure the health* by the frequent depletion of the system Sometimes, however, after having increased to a certain degree, they cease to enlarge, and thenceforth continue stationary, or gradually diminish, till scarcely any vestige remains "

There is no doubt from this that Bateman was aware of the spontaneous resolution of these lesions. The graphic description of "impetuous and alarming hæmorrhages" tells of a course of events which nowadays must be extremely uncommon but may possibly account for the surgical emergencies of which Mr Denis Browne writes.

I, along with many other dermatologists, would welcome the opportunity of seeing some of the adult patients with cavernous hæmangiomata whom Dr Colin-Jones (Jan. 2) meets so frequently in Sussex. As Mr McLaughlin states (Jan. 16), to treat or not to treat is still one of the most difficult questions in dealing with cosmetic problems.

Oxford. H. R. VICKERS

INTRATHECAL PHENOL IN THE TREATMENT OF SPASTICITY

SIR,—I wonder whether an interested reader who has treated no patients by this technique and who has made no contribution to the subject can add a comment to the recent correspondence regarding the history of this method of treatment.

Dr Maher's original work on the use of this technique in the treatment of pain, particularly in malignant conditions, is acknowledged by the writers concerned. So far, however, I have seen no reference to the fact that in the second of his papers (January 1957)[1] there is a brief but favourable mention of his use of this treatment in a case of hemiplegia with severe flexor spasms. This was, I believe, the case referred to by Dr Liversedge in his letter of Jan. 2 in which improvement has been maintained over a period of three-and-a-half years.

I am drawing attention to this reference in the interest of accuracy.

Oldham. J. STARKIE

DIAGNOSIS OF MULTIPLE PREGNANCIES

SIR,—In your annotation of Jan. 30 you make the remarkable claim that multiple pregnancy can be demonstrated by the electroencephalogram. The annotation would have little value did it not imply the maternal electroencephalogram!

It is, of course, well known that sensitive balanced recording amplifiers of the type used in electroencephalographs, when connected to electrodes placed on the abdomen of a pregnant patient, will record the R waves of the fœtal heart or hearts.[2] This technique is in general use in many obstetric hospitals and over 200 papers have been published on the subject in the past 40 years.

The time constants of the electroencephalograph type of amplifier are not ideal for the purpose and a greater degree of success can be achieved by following the design recommendations of Bell.[3] The maximum energy in the fœtal R wave occurs in about 0·02 second. An amplifier with a time constant of 0·02 second and restricted band-width will give success in almost every case. As you mention, around the 30th week of gestation recording is difficult; this is due to excess vernix caseosa.

Recent work[4] has shown that the presence of a fœtal QRS complex is not always a sign of life, for it may sometimes be obtained from a severely macerated fœtus.

In the diagnosis of multiple pregnancy it should be remembered that fœtal electrocardiography may indicate single pregnancy if one of twins is stillborn.

An advantage of using an E.E.G. machine for fœtal cardiography is that it will also read the electroencephalogram from the maternal abdominal surface and on occasions show slow waves of large amplitude. Such waves are characteristic of gross anoxia in the newborn and may indicate the same condition in the fœtus also.

University College Obstetric Hospital,

HYPOTHERMIA FOR NEUROSURGERY DURING PREGNANCY

SIR,—The report[1] on hypothermia and hypotension in a pregnant woman was of particular interest to me.

On March 31, 1958, eight months prior to the admission of Wilson and Sedzimir's patient, a woman aged 34 years, who was twenty-four weeks pregnant, was sent to the neurosurgical unit of St. George's Hospital (Atkinson Morley's Hospital) after a cerebrovascular accident.

Examination revealed a normal fœtal heart, and neurological investigation showed that the patient had bled from a right parietal angioma.

The position and size of the tumour was such that it was decided to operate under hypothermia and in the sitting position (bolt upright)—as if for a posterior-fossa tumour. Mr Wylie McKissock completely excised the tumour and the patient made an uneventful and successful recovery.

Following induction of hypothermia the fœtal heart-rate fell from a preoperative 180 to 120 per min. at 30°C, but always remained regular and returned to normal after the mother's body temperature had been restored.

The pregnancy came to full term and the child was delivered normally with the full cooperation of the mother. Both mother and child are doing well.

This case is to form part of a paper on a simplified technique for large-scale hypothermia for neurosurgery.

Cape Town. JACK LEVIN

PREVENTION AND TREATMENT OF BEDSORES

SIR,—Dr Roberts (Jan. 30) has drawn attention to a subject which deserves a very full study. 33 out of 250 patients (13·2%) treated in a geriatric unit during the past four months were found to have bedsores at the time of their admission. The stay in hospital of such patients is often prolonged (on average, it was 40 days as against 25½ days for those without bedsores). Moreover, the mortality is four times as great if pressure sores are present. The study of factors leading to the development of bedsores is therefore an important aspect of preventive medicine, and the interest of medical officers of health and district nurses in this matter is to be welcomed.

It is generally recognised that all patients who are nursed in bed—and especially the elderly—are exposed to the danger of pressure sores. The risk, however, varies considerably with different types of patient, and it is greatest for those whose general condition is poor. Because of this variation in risk the comparison of the value of different prophylactic procedures is difficult. In order that an assessment can be made more accurately we have been using a scoring system based on the patient's physical condition, his mental state, his activity, his ability to change position in bed unaided, and the degree of incontinence when this exists. The scoring can be carried out simply, and closely similar results are obtained by different observers. With this system possible scores are within the range of 5–20, and by making the score on admission to hospital and at weekly intervals the change in the patient's condition during the course of his illness can be assessed. The average score for patients who already had pressure sores was 11·0 on admission, and of those who developed pressure sores in hospital it was 12·3 initially and 11·1 at the time the sore developed. Those patients without pressure sores had an average score of 15·4.

Our preliminary observations indicate the fundamental importance of the general condition of the patient in determining the likelihood of development of pressure sores We believe that this study will also allow a comparison to be made of the effectiveness of different nursing procedures in groups of patients with a variety of diseases While it is possible that many of the traditional procedures, such as the application of spirit and powder and the rubbing in of soap, have little to commend them, the evidence so far submitted in favour of silicone creams is not conclusive At the moment the widespread use of these expensive creams as a prophylactic measure for all patients who are nursed in bed either at home or in hospital is in our opinion unjustified Large trials conducted by local health authorities and by medical and nursing teams in hospital are urgently required

A N EXTON-SMITH
DOREEN NORTON

DIAGNOSIS OF BRUCELLOSIS

SIR,—Your review (Jan 30) of my book agrees with me that we know little about this disease It was for that reason that I wrote the book on brucellosis in England I have evidently failed in my task, for your conclusion is that " many physicians will be unconvinced by the diagnosis in at least half the patients " The only reason you give for this extraordinary statement is that a rise in the titre of agglutinins after an injection of brucellin can be demonstrated in some apparently normal subjects

I took as my criteria of diagnosis those advised by Wilson and Miles in a standard textbook[1] of bacteriology and immunology In not one of my cases was " therapeutic success " used as the diagnostic weapon you suggest Every one was confirmed by either an initial agglutination titre of 1 in 80, or a positive skin test, or a fourfold rise in agglutination titre after the skin test if that was negative

Aside from this backing by eminent authorities I feel that your argument is a weak one You might as well say that because many apparently normal persons have a positive reaction to the Mantoux test you do not believe that they have ever been infected with the tubercle bacillus " Apparently normal " people may have a positive serum reaction for syphilis, toxoplasmosis, or other disease Are we therefore to abandon the use of these tests and to ignore their results ? It is true that the clinical history is important in the diagnosis of brucellosis, and indeed it is often the crucial factor in deciding whether to treat or not Wilson and Miles say " The interpretation of the agglutination test is not always easy, and demands a knowledge of the clinical history and the occupation of the patient." They also give this criterion which is less stringent than mine " A titre of 1 in 20 to 1 in 80, in the presence of clinically undulant fever, may likewise be considered as practically diagnostic of this disease "

You are also guilty of a misuse of words You say that my conclusions are dogmatic Dogmatic means based on a-priori assumptions which are incapable of proof If you read the book again carefully you will see that all the conclusions were based on the work of other investigators or my own observations They cannot therefore be called dogmatic Everyone who has anything original or unusual to put forward must expect to be disbelieved I know that the correct thing to do with an ill-informed review is to ignore it, but it is important for the sake of the patients to protest in this case So long as this unfortunate attitude of disbelief is exhibited towards the manifestations of chronic brucellosis, so long will cases be missed and much suffering which could be prevented will continue

Bath HUGH WALLIS

⁂ Of Dr Wallis' 35 proven cases, we make it that 15 were diagnosed by agglutination tests, 2 by skin tests alone, and 18 by a fourfold rise in agglutination titres *after* the injection of brucellin

We accept the evidence of the agglutination tests, with the proviso that no single test confirms a diagnosis beyond any possible doubt

Of the skin test, Wilson and Miles (p 1911) say

> " Generally speaking the reaction resembles the tuberculin reaction in denoting the occurrence of infection without giving any clear indication of its activity , it may then remain positive for months or years Great discretion has to be exercised in interpreting the test In some countries 20–30 per cent of the population may react positively to it It may be of value in survey work, but its use in the diagnosis of chronic brucella infection in the complete absence of other supporting laboratory findings should generally be discouraged It is well to remember that, particularly in persons who have been previously exposed to brucella infection the intradermal injection of the test antigen may be followed by the appearance of circulating antibodies "

The W H O committee on brucellosis believe that the intradermal test should not stand alone as supporter of the diagnosis

As to the significance of a fourfold rise in titre after injection of brucellin, we have seen no convincing evidence to justify Dr Wallis' interpretation Brucellin, like any other antigen, produces antibodies the amount produced is—to judge by experience with such things as T A B —*very variable* If the patient has had a previous infection—i e, has a positive brucellin reaction—the titre will rise even higher than it will in a virgin, and in the circumstances we feel that Dr Wallis places too much reliance on this serological reaction in making a diagnosis That was one reason why we described his conclusions as " dogmatic "

Re-examining the 35 case-histories in Dr Wallis' book, we would say that half are probably brucella infections, and of the rest, some may be psychosomatic ailments and some P U O s—and there are many causes of pyrexia in children about which we know little or nothing Dr Wallis' view seems to be that once a child has had a brucella infection any future vague illness is the same thing —ED L

HYPNOSIS AND UNREGISTERED PRACTITIONERS

Dr A A MASON, secretary, British National Division, International Society for Clinical and Experimental Hypnosis, writes

" I have been approached by Dr Ainslie Meares, the Australian president of the society, and Dr H Grant-Whyte, a member of the South African Medical and Dental Council, both of whom are investigating the problem of lay hypnotists and the possible harmful effects which can be caused by the use of hypnosis by unqualified practitioners Dr Grant-Whyte has approached the Minister of Health in an attempt to get legislation in South Africa along the lines of the British Hypnotism Act, 1952, and also in an attempt to restrict the practice of unregistered and untrained persons It would be of great assistance to both these doctors to have available all the details of harmful effects which have followed the use of hypnosis by unregistered practitioners, and indeed if sufficient evidence is present it could stimulate similar action in this country I should be grateful, therefore, if any doctors who have evidence from their own practice of patients suffering harm following the use of hypnotism by unqualified practitioners could communicate the details of such cases to me at 24, Avenue Road, Regent's Park, London, N W 8 Of course, I need hardly assure the doctors and their patients that this matter will be treated in the strictest confidence "

Parliament

Handicapped Refugees

In the House of Lords on Feb 2 Baroness **Elliot of Harwood** asked if we could not mark World Refugee Year by admitting further immigrants into this country The appeal for money was being very successful and the target of £2 million would be exceeded. About £125,000 had been already allocated for rehousing outside the camps in Austria, Germany, and Italy large families and old and infirm people, both groups which were difficult to move to other countries £5000 was to be used for medical advice and to make a survey of people who had been many years in camp and whom it was difficult to take straight out and put into the world

But the greatest stumbling-block to clearing the camps was the difficulty of resettling the handicapped refugees They were brought before tribunals and turned down because of illness or suspected tuberculosis and they and their families had to remain in camp In November the Government had given permission to bring in 210 handicapped refugees and their families But there was still a great need for us to be more generous about handicapped refugees The most recent figures showed that the number of handicapped refugees in camps is 10,000, comprising families of which one member is handicapped, and the number outside camps is 17,850 Of course, only a small proportion of handicapped refugees would want to come here. Some of them wanted to be settled in the area in which they had been working or had been educated, and many wanted to go to the New World to get away from European problems But we could still take more here, and she asked the Government to consider altering slightly some of the terms under which people were brought here, and to be a little more generous, possibly, in statutory help for families should they by any chance fall again into difficulty after some years or not be in full employment

Lord **Shackleton** pled for a more liberal application of some of the regulations He thought that experience was beginning to show that some health regulations were completely pettifogging—for example, the unwillingness to admit people who had had tuberculosis, who had been cured, and were now living useful lives He thought that we were putting unnecessary obstacles in the way, and in the process we and other countries had created great unhappiness

Lord **Amulree** agreed that it was a terrible thing if one member of a family which was acceptable here was found to have tuberculosis Until quite lately that was an absolute bar to their admission. We all knew that in this country tuberculosis, particularly of the chest and lungs, was, to a large extent, a curable disease Why were we so frightened of admitting people with this disease when there were facilities for treatment and good prospects of cure? He thought it improper that the Government would accept financial responsibility at no time for these unfortunate people One could see that for the first few years they were here they should be supported by voluntary bodies, but it was expected that most of them would obtain jobs and settle down to become perfectly good, reputable, and productive citizens of this country Why voluntary bodies who had money should be forced to keep sums aside in case these people fell on evil days in ten, twenty, thirty, or forty years' time he did not understand, and he trusted the Government would see their way to making these people eligible, when they came here as refugees, for the ordinary kind of benefits that a person living in this country would expect to obtain. The sum could not be large, but it was a very big sum for the voluntary organisations to have to put aside and tie up

Baroness **Swanborough** said that the family unit was always of paramount importance. When a family was not only a family, but was the only asset that a small set of people possessed, it assumed very special proportions indeed She felt that we should do our utmost to preserve the family in its entirety The handicapped refugee families had been faced with years and years of misery in order not to break up their own unit. Because of a brother with tuberculosis, or a mother with cancer, or a small child who, through a brain injury, could never be a normal child, a whole family had lived all these years in a dreadful and unhappy way

Government regulations, framed meticulously by men and women of good will but of chairbound experience, had forbidden the entry into various countries of people with disabilities, specified diseases, and handicaps The debate had still ignored the fact that we were being allowed to bring into the country only people with handicaps that could be cured She hoped that the Government would permit the entry within each family of a diseased or an incurable person who, despite the fact that he or she could not recover, could be looked after by his own family

The Marquess of **Lansdowne** said that he had listened to the debate with sympathy but he felt that we should remember that a quarter of a million people had been received into this country, and that 1 in every 200 of the people of the United Kingdom at the present time had been refugees 21 tuberculosis refugees had lately been admitted to the country, but it was correct that so far the regulations allowed only for curable cases He believed that that attitude might be very sympathetically considered by the Department concerned Wherever it was economically possible, the Government would continue to do everything in their power to unite families Where there was a refugee settled in this country and earning money, members of the family were already allowed to come in. He believed that both the Home Office and the Ministry of Health tried to view this problem in a sympathetic way A further survey of handicapped refugees was shortly to be made. He believed the opening of the gates to the handicapped refugee was an important achievement

Public Health Laboratory Service Bill

In introducing this Bill on Feb 4, Viscount **Hailsham** explained that the P H L S had been started shortly before the late war by the Medical Research Council at the request of the Committee of Imperial Defence. Its original object was to provide a defence against possible enemy use of bacteriological warfare and against outbreaks of epidemic diseases In the event, the service was not used to deal with any major emergency of this kind On the other hand it came to be used by medical officers of health as a valuable aid to their ordinary work. Only in the areas of some of the larger local authorities had any such service previously been available. Indeed, the main reason for creating the service had been the inadequacy of the arrangements before the war for public-health bacteriological work. Thus, it came about that a service which had been designed for an emergency became an indispensable part of normal peace-time administration. It was therefore decided after the war to maintain it as part of the regular machinery for the diagnosis and control of infectious diseases The M R.C had continued to administer it as agents for the Minister of Health.

The P H L S at present consisted of a central laboratory, 8 regional laboratories, and 51 area laboratories There were several special reference libraries, some at the central laboratory and some in other institutions The service was considered now to be fully developed, and no increase in the number of laboratories was planned The staff numbered 1068, of whom 126 were medically qualified The annual cost of the service was about £1,262,000

The M.R.C had for some time been anxious to divest themselves of responsibility for the service, and to substitute a permanent organisation responsible to the appropriate executive department for what was always an anomalous and temporary arrangement. The work of the P H L S was really peripheral to the M.R C 's interests, for they were mainly concerned with research, while the service, though scientific, was largely routine and research was included only as a secondary function There was some inconvenience in the anomaly that the M.R C were responsible for their normal activities to the relevant Privy Council committee, and for the P.H L S to the Minister of Health The position was also somewhat embarrassing for the M.R.C as employers of labour The level of remuneration of their own staff was related to that of the staffs of universities The remuneration of the P H L S staff was related to that of staffs of hospitals in the National Health Service

The executive work of the P H L S had remained with the M R C 's headquarters staff, but the ordinary work of the Council and of their headquarters staff had continued to grow, so that it had now become necessary for the P H L S to be given its own administrative machinery as soon as possible so as to release the headquarters staff of the M R C Accordingly, it was decided to introduce this Bill which would enable the Minister of Health to administer the service through a new Public Health Laboratory Service Board which he would appoint

The board would be a separate entity, with legal status, and it would employ staff and hold property in its own name It would be analogous to a regional hospital board—that is to say, it would administer the service as the agent of the Minister It would be appointed by the Minister and its staff would not be Civil Servants It would be subject to the directions of the Minister, whose control of the service would thus remain more or less as at present

The board would consist of a chairman and one other member, both medically qualified, two members appointed after consultation with the M R C, two members with experience as bacteriologists, two members who were medical officers of health of local authorities, and two members with administrative experience

Lord Taylor described the P H L S as a kind of national medical Scotland Yard It differed only in that it had its peripheral units scattered all round the country and did not have to wait for a county police force to call it in It did, however, have to be called in by somebody, and the people who called it in were medical officers of health, hospitals, or local doctors One great feature of the service was that staff had always been available for personal consultation They had come out to see cases, investigate problems on the spot, and help doctors with any kind of epidemiological problem

The P H L S had also done an immense amount of research, and he was a little sorry to hear Viscount Hailsham say that the bulk of its work was routine and that it was not primarily a research organisation Lord Taylor hoped that this transfer of functions would not entail any lessening of the research activities of the service The service had put Britain in the forefront of bacteriology and epidemiology The World Health Organisation had recognised the central laboratories of the service at Colindale as the World Influenza Centre It had also a virus reference library, a mycological reference library and an air hygiene unit It had an epidemiological research unit at Cirencester run by a part-time general practitioner On the purely bacteriological side the service maintained centres which concerned the whole of Europe and the Commonwealth for serological typing, particularly of salmonella and dysentery organisms Research ranged from bacteriological structure and metabolism to such practical questions as the design of operating-theatres and the bacteriology of public telephones and iced lollipops

Viscount Hailsham had also mentioned that the service was primarily linked with the medical officers of health Lord Taylor believed that it was also linked, perhaps more closely than was generally realised, with the hospital services In some places the public-health laboratory functioned as a general-hospital bacteriological laboratory, doing the routine bacteriology for that hospital and for the general practitioners as well as its own specialised work on milk, water, shell-fish, and ice-cream In other places it did specialised work only It had been suggested that the right thing would be to make the P H L S part of the regional hospital board service But Lord Taylor was sure that the decision taken by the Government was the right one The service should be kept as an entity, for bacteria knew no regional boundaries Moreover, there must be a central reference organisation, if these germs and viruses were to be identified in the increasingly difficult varieties in which they occurred

Turning to the membership proposed for the new board, Lord Taylor said that he could see no reason for the stipulation that the chairman should be medical It was widely believed in the P H L S that the intended chairman might be the chief medical officer of the Ministry of Health Lord Taylor thought this a bad idea, because the chief medical officer was an exceedingly busy person and because the board should have an autonomy, a vigour, and a life of its own It should be the servant of the Minister and subject to his general direction, but it should bat on its own wicket and not be tied to the Ministry The job of chairman called for someone who would give a good deal of time to it 40 or 50 laboratories were scattered about the country If the chairman went round and saw every laboratory once a year it would be for the good of the staff Lord Taylor regretted that there was no representative of the hospitals, though the service was closely linked with the hospitals, or of the general practitioners, though the general practitioners were exceedingly interested in the kind of research which the service did He was also disappointed that there was no representative of the staff on the board

Lord Amulree suggested that, as the board would work closely with the regional hospital boards, it might not be a bad idea to have on the board one of the senior medical officers who advised the hospital boards He, too, hoped that there would be some representation of the hospital service and general practice Another important point was that there should be one lay member

Viscount Hailsham agreed that to keep a service alive it was necessary to include research in its activities, and the P H L S 's research activities were important and creditable It was mainly for that reason that it was proposed that two members of the board should be appointed after consultation with the M R C The composition of the board would probably be considered on the committee stage of the Bill Though the schedule did not contain a direct reference to a hospital representative, a number of medically qualified people would have to be appointed to the board, including bacteriologists and others, and he would have expected to find that the board contained names which came from the hospital service

Powers of Subpœna

On Feb 2 at the end of the committee stage of the Professions Supplementary to Medicine Bill a Government amendment was carried to remove the power of subpœna from the disciplinary committees to be set up under the Bill Miss Edith Pitt, parliamentary secretary to the Ministry of Health, explained that the Government thought that the subpœna provisions should be omitted until the Simonds Committee had reported The matter could then be reconsidered The Bill would still enable the disciplinary committees to administer oaths It was hoped that the Simonds report would be ready before the Bill left the floor of the House

QUESTION TIME

General Practitioners' Central Fund

Mr Barnett Janner asked the Minister of Health how much Exchequer contribution had been deducted annually from the General Practitioners' Central Fund since 1955, how it was computed, and what was the relationship between the Exchequer contribution annually deducted from the Fund and the employers' contribution to the National Health Service compulsory superannuation scheme, and how he proposed to increase the employers' contribution so as not to reduce the sum to be distributed to general practitioners Mr Walker-Smith replied The amount of the Exchequer superannuation contribution deducted from the Central Pool is the aggregate of the employers' superannuation contributions paid by the executive councils for the general medical practitioners with whom they are in contract The amounts involved were, for Great Britain

	£
1955–56	3,529,607
1956–57	3,569,494
1957–58	3,809,181

The superannuation position of practitioners cannot be considered further until the Report of the Royal Commission on Doctors' and Dentists' Remuneration has been received and considered I have, however, given an assurance that the supplementary employer's contribution which is being introduced to help liquidate the deficiency in the health service superannuation scheme will not have the effect of reducing the current net remuneration of general practitioners The detailed method of achieving this has still to be discussed with the profession.

Mr JANNER In considering this matter, will the Minister take into account the fact that the proportion which is being deducted, which is 8%, was given as 2% less by the actuary in 1955? In view of that, will he refund to the general practitioners the loss they have incurred thereby? Mr WALKER-SMITH I do not think that that point arises The general situation which the hon Gentleman wishes to safeguard is really dealt with in the penultimate sentence of my answer

Lay Hospital Staff

Dr A D D BROUGHTON asked the Minister the number of personnel, other than medical and nursing staff, employed in hospitals in England and Wales when the National Health Service came into operation in July, 1948, and the number at the latest convenient date Mr WALKER-SMITH replied In round figures 197,000 at the end of 1948 and 250,000 at the end of 1958 This includes professional, technical, works, maintenance, domestic, administrative, and clerical staff

Preludin (Phenmetrazine)

Mr MARCUS LIPTON asked the Home Secretary whether he had now received the report of the Poisons Board on 'Preludin', and whether he would now ban the sale of this drug without medical prescription.—Mr R. A. BUTLER replied I have now received from the Poisons Board a report concerning a recommendation that a number of substances including preludin should be supplied only on prescription Subject to the consideration of any representations by those concerned, I propose to accept this recommendation and to give it effect as soon as practicable

World Refugee Year

Mr D E. C. PRICE asked the Home Secretary whether, in pursuance of the support of the World Refugee Year, he would admit another 1000 refugees to this country before Easter—Mr R. A. BUTLER replied Arrangements are being made in consultation with the United Kingdom Committee of the World Refugee Year, to ascertain the number of specially handicapped refugees who wish to come to this country and can be adequately sponsored by the voluntary organisations I shall consider the matter further when this information is available.

Medicine and the Law

A Difficult Patient

SECTION 172 of the Public Health Act, 1936, dealing with precautions against exposure of the public to infectious diseases, sets out the conditions under which action may be taken to restrain infectious persons who refuse to accept precautionary measures This section of the Act was reluctantly invoked in Oxford last week to send to hospital for three months a woman of 52 who was known to have had pulmonary tuberculosis for twelve years

In April, 1948, after a hæmoptysis, she was found to have pulmonary tuberculosis with a probable cavity, but she refused to attend the chest clinic. She was offered a bed in hospital at any time convenient to herself but again refused. In July, 1948, she was found to be pregnant. Home conditions were very bad, and 4 adults and 2 children were occupying one room in a basement, so the family was ultimately rehoused in August, 1949 During this time repeated requests to attend the chest clinic were ignored. On one occasion she promised to attend if transport was provided, but an ambulance called three times without success Nothing further could be done, and the family was removed from the chest-clinic register

In August, 1951, another attempt was made to get her to the clinic, but it failed. Finally in March, 1954, she became very ill and she was admitted to hospital as an emergency Her sputum was loaded with tubercle bacilli and she had gross bilateral tuberculosis She remained in hospital having chemotherapy for three months, and then discharged herself against advice. She still had extensive and very unstable cavitated disease with a positive sputum, but there had been definite improvement. One of her children had phlyctenular conjunctivitis and was under care for several years Her other child also had primary tuberculosis, for which his mother refused hospital treatment.

After her discharge, there was a period of intermittent observation at the clinic and evidence of some improvement in her tuberculosis In September, 1954, she described symptoms which may have been due to drug intolerance, and streptomycin was withdrawn, although she was supposed to continue on P.A.S and isoniazid. In December, 1956, laryngeal-swab culture was positive for tubercle bacilli Further attempts, both by the clinic staff and by the medical officer of health, to get her to attend during 1957 were unsuccessful. At the end of 1958 it was thought that she was working in a canteen. In January, 1959, she was brought to the clinic by the chief public-health inspector in his car Bronchial lavage gave a positive culture for tubercle bacilli, which showed normal sensitivity to anti-tuberculous drugs X-ray examination showed extensive fibrotic disease which had not spread since November, 1956 She maintained that she had had chemotherapy ever since she last attended the clinic, but this was not confirmed by the doctor she named. Last December bronchial lavage was again positive and radiologically the disease had extended.

It was clear that she was infectious to other persons, that she would accept treatment only under duress, and that her promises to carry out treatment at home were quite unreliable On Feb 4 the Oxford magistrates granted an order to Oxford City Council that she should be taken to the Osler Hospital for three months

We are indebted to Dr F Ridehalgh for supplying this information.

Obituary

EILEEN MARY HICKEY

M D, B Sc Belf, F R C.P I, D.P.H

Dr Eileen Hickey, who died on Feb 3 at her home in Belfast at the age of 75, was distinguished both as a physician and as a member of the Parliament of Northern Ireland

In her early life she entered the Civil Service, and it was not until she was in her early thirties that she decided to qualify in medicine. She returned to Belfast and studied at Queen's University Her student career was marked by enthusiasm and by impatience to be qualified, and also by a positive enjoyment of the written examination which amazed her more usually pen-tied contemporaries She graduated M.B with first-class honours in 1921 and two years later obtained the M.D with a gold medal Her career as a physician was based on the Mater Infirmorum Hospital in Belfast, and she became senior physician and a member of the board of governors She examined in medicine at the university, was for many years a member of the senate, and was the first woman to be elected president of Queen's Graduates Association.

A H B writes

"Eileen Hickey had a ready pen and spoke fluently and entertainingly It was no surprise to her fellow graduates when she was returned in 1949 as one of the four members representing the university in the Northern Ireland Parliament. She was returned as an Independent in a Parliament where politico-religious feeling ran high. She was again returned in 1953, but owing to failing health did not seek re-election in 1958

"She had many outstanding qualities Among them were a great sense of responsibility in everything she undertook and a deep sympathy for old people Her indignation was easily aroused on behalf of any person or cause that she thought unfairly treated She was a bonny fighter and a most staunch friend She worked hard for the cause of old people's homes when she was a member of the Council of Social Service in Northern Ireland, and, after the late war, she organised the sending of parcels to refugees and others impoverished by their war-time experiences She had a great love of gardening and of flowers

" She faced with fortitude her years of declining health and did not allow herself the indulgence of self-pity Her Church was very real to her and was a support and an abiding interest She will be remembered by her university as a great character, and by her friends for her lively wit, dauntless spirit, and many acts of great kindness "

RAYMOND EBENEZER APPERLY

M R C S , F F A R C S , D A

Mr Raymond Apperly, consulting anæsthetist to the Middlesex Hospital, London, died on Jan 29 at Evesham, at the age of 76

He was born in Stroud, Gloucestershire His father, Mr Ebenezer Apperly, L D S , had been a dental student at the Middlesex Hospital, and in due course Raymond, following what was becoming a family tradition, joined the medical school. He qualified in 1907, and after holding house-posts at the Middlesex he was appointed anæsthetist to the Hospital for Sick Children, Great Ormond Street In 1910 he joined the anæsthetic department at the Middlesex Hospital and later became lecturer in anæsthetics at the medical school. In 1931 he succeeded Dr Herbert Charles as senior anæsthetist He took the D A in 1935 and was elected F F A R C S in 1948

H P C , who was a student with Apperly nearly sixty years ago, writes

"Raymond Apperly was a cheerful, friendly soul, popular alike with men, women, and children He had an extensive private practice, as I discovered if he was ill To give an anæsthetic to a patient who had already been sent to sleep by Apperly was not easy, for their disappointment was often so evident One Saturday, years ago, the school doctor in Sussex phoned that my son had an acute appendix which should come out that day when he arrived by ambulance At 5 P M Apperly appeared with the surgeon. Some time later I found out that he was spending the day at Lancing with his son but had cut it short to help a friend. Such was the man A delightful colleague who will be remembered with affection by the old brigade "

Mr Apperly leaves a widow, a daughter, and a son who is in practice at Evesham

ALEXANDER HUGH DICKSON SMITH

M C , T D , M B. Edin , D L

Dr Smith, who died on Jan 31 at the age of 69, spent many years in practice in his native Llanelly and played a large part in the settlement of the " Llanelly dispute " of the mid '30s

He was educated at Llandovery College and the University of Edinburgh, where he qualified in 1914 The same year he joined the R A M C and went to France, where he became attached to the Guards Division He was awarded the M C for conspicuous bravery in 1917 He served later with the 3rd and 29th Divisions and finished his war service in India On his return to Llanelly he at once entered general practice Soon afterwards he joined the staff of Llanelly and District Hospital He did most of the surgical work there and became the first honorary radiologist to the hospital

As a member of the Territorial Association he was sent on the outbreak of the late war to France with the rank of lieut-colonel He returned from France in 1940 and thereafter acted as O C to units in Western Command At this time he gave up his general practice, but he remained extremely active in medical affairs in South Wales he was chairman of many committees, including the Ministry of Pensions boards for Swansea and Carmarthenshire, the committee under the Disabled Persons Act, and the Carmarthenshire panel, insurance, and executive committees He was high sheriff of the County of Carmarthen for 1944 and 1945, and deputy lieutenant in 1952

He married Joan Margaret, daughter of the late Dr Hugh John She survives him, with their daughter

Notes and News

WORLD HEALTH ORGANISATION

THE executive board ended its session on Feb 1 The proposals of the director-general, Dr M G Candau, for W H O 's 1961 programme and regular budget of $18,569,620, were unanimously recommended to the Health Assembly which opens in Geneva on May 3 The board approved steps taken towards the building of a new headquarters for the Organisation in Geneva On a site not far from the Palais des Nations, this will cost about 40 million Swiss francs, of which 20 million is to come from the Swiss Federal authorities in the form of an interest-free loan, and 10 million is to be made available by the Republic and Canton of Geneva, which is also giving the site The architectural competition closes on April 14

Only about 1 million dollars is now needed to finance W H O 's share of the costs of malaria eradication for 1960, but $6 4 million is needed to ensure continuation of the work in 1961

Figures released on Jan. 29 show that the world incidence of plague was as low last year as in 1958, fewer than 300 cases of human plague were officially reported in ten countries of Africa, America, and Asia (outside continental China) The occurrence of " accidental " single cases (in the United States of America and Madagascar) and of small foci in areas which had been apparently free from human cases for one or more years (in Northern India and in the Union of South Africa) indicates that the infection is maintained among rodents in wide areas of the three continents Burma notified the highest number of cases (98)

Cholera incidence in 1959 was unusually low in India, and, in spite of the presence of the disease in Thailand and its considerable increase in East Pakistan during October and November, fewer than 42,000 cases were officially reported in Asia (excluding China), compared with about 95,000 in 1958 and 64,000 in 1957 " In India the situation was probably the most favourable on record Less than 14,000 cases were provisionally notified against 67,000 reported in 1958 "

SUPPLEMENTARY ESTIMATES

THE supplementary estimate for the National Health Service in the current financial year [1] shows an increase for England, Wales, and Scotland of £25,600,000, bringing the total net cost to £562 million Of the additional sum £15 million goes to the revenue account of hospital boards, mainly to meet salary and wage increases, £6 million to the pharmaceutical services because of an increase in the number of prescriptions and higher average costs per prescription, and £1$^{1}/_{2}$ million to meet the increased demand for poliomyelitis vaccine

O & M

FIRST reaction to the latest report [2] by the Hospital Organization and Methods Service may be that it is all obvious and simple so it is, but there is no doubt that it is also a necessary and sad commentary on some aspects of the National Health Service. The report concerns the activities of chest clinics, including the design of an outpatient appointments system, the efficient use of the time of staff and patients, and the keeping of medical records Chest clinics are used merely as an illustration. They are well chosen for this purpose, for they are often relatively small self-contained units handling large numbers of " new " and " old " patients, and therefore easy and profitable to study The fact that they are the subject of this report does not mean that they are either better or worse organised and run than any other branch of the N H S

The instructions for studying the problem of efficient flow of patients in a clinic are clearly expressed and easy to carry out It is almost a shock to see a whole-page diagram whose sole purpose is to illustrate that the rate of flow is determined by the speed of the slowest process The same applies to the movements of armies and was discovered long ago But if this and similar " rules " were widely acknowledged and acted on there would be no need for O & M surveys The report concludes

> " The great bulk of matters dealt with here is concerned with efficiency of a fairly mechanical kind It is recognised that this efficiency ranks only second in importance to the standard of medical and nursing care which is given to the patients These two aspects are not, as is sometimes assumed, conflicting, but complementary Medical care is hampered if case-notes go astray, and medical skill of the highest quality is wasted if the patients become disgruntled and do not come to take advantage of it If, on the other hand, medical skill is practised in an environment of orderliness, if waste of time and effort are eliminated, and if the general, as distinct from the purely medical, well-being of the patients is secured, the maximum benefit will be derived from the services provided "

APPROVED NAMES FOR DRUGS

THE British Pharmacopœia Commission has issued the following new supplementary list of approved names

Approved name	*Other names*
Bamethan	2-*n*-Butylamino-1-*p*-hydroxyphenylethanol Vasculit is the sulphate
Bendrofluazide	3-Benzyl-3 4-dihydro-7-sulphamoyl-6-trifluoromethyl-benzo-1 2 4-thiadiazine 1 1-dioxide Aprinox
Carbolonium Bromide	Hexamethylenebis (carbamoylcholine bromide) Imbretil
Carisoprodol	2-Carbamoyloxymethyl-2-*N*-*iso*propylcarbamoyloxypentane
Cetylpyridinium Chloride	1-Hexadecylpyridinium chloride Ceepryn
Cyclandelate	3 3 5-Trimethyl*cyclo*hexyl mandelate Cyclospasmol
Cyclophosphamide	2-[Di-(2-chloroethyl)amino]-1-oxa-3-aza-2-phospha*cyclo*hexane 2-oxide Endoxan, Cytoxan
*Dextropropoxyphene	*a*-(+)-4-Dimethylamino-1.2-diphenyl-3-methyl-2-propionyloxybutane Darvon is the hydrochloride, Doloxene is the hydrochloride
Dimethoxanate	2-(2-Dimethylaminoethoxy) ethyl phenothiazine-10-carboxylate
Diphenadione	2-Diphenylacetylindane-1.3-dione Didandin, Dipaxin, Oragulant
Diphenoxylate	Ethyl 1-(3-cyano-3 3-diphenylpropyl)-4-phenyl-piperidine-4-carboxylate
Disulphamide	5-Chloro-2 4-disulphamoyltoluene Disamide
Heptabarbitone	5-Ethyl-5-*cyclo*hept-1 -enylbarbituric acid Medomin
Nialamide	*N*-(2-Benzylcarbamoylethyl)-N -*iso*nicotinoylhydrazine Niamid
Phenazocine	2′-Hydroxy-5 9-dimethyl-2-phenethyl-6 7-benzomorphan
Phenprocoumon	4-Hydroxy-3-(1-phenylpropyl)coumarin Marcoumar
Salazosulphadimidine	4 -(4 6-Dimethylpyrimid-2-ylsulphamoyl)-4-hydroxy-azobenzene-3-carboxylic acid Azudimidine
Sulphaphenazole	5-*p*-Aminobenzenesulphonamido-1-phenylpyrazole Orisulf
Tetrahydrozoline	2-(1 2 3 4-Tetrahydro-1-naphthyl)imidazoline Tyzanol is the hydrochloride
Trimustine	Tri-(2-chloroethyl)amine Trillekamin

* Replaces the approved name propoxyphene for α-(+)-4-Dimethylamino-1 2-diphenyl-3-methyl-2-propionyloxybutane

Proprietary name	*Approved name reference*
Aprinox	Bendrofluazide
Azudimidine	Salazosulphadimidine
Ceepryn	Cetylpyridinium Chloride
Cyclospasmol	Cyclandelate
Cytoxan	Cyclophosphamide
Darvon	Dextropropoxyphene
Didandin	Diphenadione
Dipaxin	Diphenadione
Disamide	Disulphamide
Doloxene	Dextropropoxyphene
Endoxan	Cyclophosphamide
Imbretil	Carbolonium Bromide
Marcoumar	Phenprocoumon
Medomin	Heptabarbitone
Niamid	Nialamide
Oragulant	Diphenadione
Orisulf	Sulphaphenazole
Trillekamin	Trimustine
Tyzanol	Tetrahydrozoline
Vasculit	Bamethan

Association of Industrial Medical Officers

This Association is offering in 1961 a prize (50 guineas) for an essay from a member on research on occupational health. Further details may be had from the hon secretary of the Association, 47, Lincoln's Inn Fields, London, W C 2

University of Oxford

Sir Lindor Brown, Jodrell professor of physiology at University College, London, has been appointed Waynflete professor of physiology in succession to Prof E G T Liddell, who is retiring under the age-limit

Sir Lindor, who is 56 years of age, was educated at the Boteler Grammar School, Warrington, and the University of Manchester, where in 1924 he took his B SC with honours in physiology and was awarded a Platt physiological scholarship The following year he took his M SC In 1928 he graduated M B, and in the same year he was appointed lecturer in physiology at the University of Leeds He worked there on gastric innervation with the late B A McSwiney and on transmission through sympathetic ganglia In 1934 he joined the scientific staff of the Medical Research Council, working in Sir Henry Dale's laboratory on transmission at nerve-endings by acetylcholine In the early years of the war he worked on military problems, spending some time in the laboratory at Lulworth In 1942, when the Royal Naval Personnel Research Committee was set up, he became its secretary, and until 1945 he was directing work in his own laboratory on underwater physiology, dealing particularly with problems affecting submarine crews and divers using self-contained gear He was appointed to the Jodrell chair in 1949 He was a member of the Medical Research Council from 1951 to 1955 and of the Advisory Council on Scientific Policy from 1956 to 1959 He has been successively secretary of the Physiological Society, an editor of its journal, and foreign secretary He was elected F R S in 1946, and became biological secretary of the Royal Society in 1955 and a vice-president in 1956 He was elected F R C P in 1958 In 1947 he was appointed C B E, and in 1957 he was knighted

University of Cambridge

On Jan 23 the following degrees were conferred

M B, B Chir—A J H Nix

M B—*J D Allison, *John Farmer, D H Keeling, C J F L Williamson

*By proxy

University of London

Dr H O Schild, reader in pharmacology at University College, has been appointed to the chair of pharmacology at the college

Dr Schild took the degree M D Breslau in 1932 and joined the scientific staff of the Medical Research Council at the National Institute for Medical Research in London He has worked in the departments of physiology and pharmacology of Edinburgh University, and in 1937 he joined the staff of the department of pharmacology at University College, London In 1935 he took the PH D Edin and in 1950 the D SC Lond His published work includes studies on the principles of biological assay, drug antagonism, and an extensive series of papers on the mechanism of the anaphylactic reaction and histamine He is joint editor of the 1959 edition of *Applied Pharmacology*

Dr W F Widdas, reader in physiology at King's College, has been appointed to the chair of physiology at Bedford College

Dr Widdas qualified M.B from the University of Durham in 1938 and has since taken the degrees of PH D and D SC of the University of London He held a senior lectureship in physiology at St Mary's Hospital Medical School before taking up his present post During the late war he served with the R A M C with the rank of major

Dr Hermann Lehmann, senior lecturer in chemical pathology at St Bartholomew's Hospital Medical College, has been appointed to the readership in that subject at the college

The title of reader in chemical pathology has been conferred on Dr G R Webster in respect of his post at Guy's Hospital Medical School

Royal College of Physicians of Ireland

At a meeting of the college on Feb 5, with Dr P T O'Farrell, the president, in the chair, the following were admitted to the licence and membership

Robert Carroll, D C Curtin, J P Duffy, J S Wright

Royal Australian College of Physicians

The following officers of the college have been elected for 1960–62

President, T M Greenaway (Sydney), vice-presidents, F R Hone (Adelaide), H M Rennie (Sydney), E H Roche (Auckland), censor-in-chief, K B Noad (Sydney), hon treasurer, G B D Hall (Sydney), hon secretary, R L Harris (Sydney)

Royal College of Physicians of Edinburgh

At a meeting on Feb 2, with Dr A Rae Gilchrist, the president, in the chair, the following were elected to the membership

A L K Rankin, Raghunath Singh Hoon, I S Trotter, Bomullage Dilipkumara Dharmasena, Mohd Hayat Zafar, K D Coorey, Mary Cherian, R S Wells, S J Surtees, G P Lewis, D J Woods, W A G Roper, Ramji Singh, Sushil Kumar Mitra, Bhattarahalli Gururao Srinivash Murthy, Colin Protheroe, J C Maclaurin, Prasanta Kumar Basu, Kandathil Mammen Cherian, Tin Ohn, Nabiha Hasan Rizavi, Krishna Kant Sinha, Roop Kishore Seth, Ma Hnin Yee, Kathleen A Irvine, G W Fenton, Francis Moran, Narayanarao Ambajeerao Jadhav, Freda M Paul, Ishaa Sh'Aibu Audu, Chinganezhath Krishnan Ramachandran, Yip Chong Wong, J S Fleming, Vetherednam Thuraisingham, F P Retief, J G Richards, Manasija Sarkar, L L Wilson, Kottaram Venkatachala Sarma Krishna Das, Upamaka Brahmaji Rao, F Po-Tun Fok, W E Ince, I T Draper, Sydney Louis, E S Paykel, Anupam Das Gupta, D F Scott

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the Faculty on Feb 1 with Mr Arthur Jacobs, the president, in the chair, the following were admitted to the fellowship

Perinkulam Krishnaswami Ramaswami qua physician, Ratan Lal Agarwal, Alumooti David George qua surgeon

Lady Tata Memorial Trust

The trustees of this fund invite applications for grants, scholarships, and fellowships for research on blood diseases, with special reference to leukæmia

Programmes of research on any aspect of malignant disease which may throw light on problems of leukæmia will be considered and awards may be made to investigators of any nationality, working in any country where payment can be made Application forms may be had from the secretary of the (European) Scientific Advisory Committee of the Trust, Chester Beatty Research Institute, Fulham Road, London, S W 3 Applications must be submitted before March 31

Scottish Health Services Council

Mr John Dunlop has been appointed chairman of the council in succession to Prof G L Montgomery

International Congress on Alcohol and Alcoholism

This congress will be held from July 31 to August 5, in Stockholm Further particulars may be had from the congress secretary, Box 5071, Stockholm, 5, Sweden

Universities Federation for Animal Welfare

The annual general meeting of this Federation will be held on Tuesday, Feb 16, at 6 P M, at the Conway Hall, Red Lion Square, London, W C 1, when Major C W Hume will report on his recent visit to the conference of the Animal Care Panel in America At 8 P M there will be a brains trust

Surgeon Captain F P Ellis, of the Medical Department of the Admiralty, has been awarded £100 and a medal by the Chadwick Trust in recognition of his work during the last five years in promoting the health of Royal Navy personnel

Courses for candidates for the D M R.D and D M R T, starting in October, are now being organised by the Faculty of Radiologists Further particulars may be found in our advertisement columns

The British Council for Rehabilitation and the University of St Andrews will hold a conference from March 29 to 31, at Queen's College, Dundee The subject will be rehabilitation—its industrial and social implications Further particulars may be had from the general secretary of the Council, Tavistock House South, London, W C 1

The North of England Otolaryngological Society will hold a meeting in Hull on Saturday, Feb 20, at 2 P M

Appointments

UNIVERSITY DEPARTMENT OF MATHEMATICS, THE UNIVERSITY, GLASGOW

Thyrotoxicosis may be treated surgically, by radioactive iodine, or by one of the antithyroid drugs Whichever method is chosen the clinician must decide whether or not his treatment has been effective His conclusions are based on the gradual disappearance of a number of abnormal symptoms and signs Different observers may attribute differing degrees of significance to these changes and for this reason it is desirable that the same person should carry out the interview and examination at each visit. But even when this is practicable the observer may find it difficult to decide on the relative importance which should be attached to different clinical features especially if they are in conflict—for example, to a reduction in the degree of tachycardia combined with a failure to gain weight That the inaccuracy inherent in a purely clinical assessment of the regression of the disease is real is shown by comparing the conclusion of Bartels (1945) that thiobarbitone is 12 times more active in thyrotoxicosis than thiouracil with that of Astwood (1945) who found it to be only twice as active.

The alternative method of following a patient's progress by repeated estimations of the basal metabolic rate (B M.R.) is time-consuming and inconvenient for the patient In addition it is necessary to allow for the effect of training, and because of the wide normal range the method is applicable only to groups of patients and the results must be treated statistically Since diagnostic tests using radioactive iodine give misleading results in a patient receiving an antithyroid drug this parameter of thyroid function cannot be used in assessing therapeutic response.

We have approached this problem of assessing the response to treatment in a new way In a previous investigation we were able to allocate figures indicating the relative diagnostic value of the various symptoms and signs of thyrotoxicosis To do this we carried out an analysis of their comparative frequency in patients with the disease and in normal individuals From these we derived a total score which we called the diagnostic index and which we have been able to show has about the same degree of diagnostic accuracy as estimations of the B M R , or the results of radioactive-iodine studies (Crooks et al 1959) By removing from the list of these diagnostic features of thyrotoxicosis those which are unaffected by treatment we have now constructed a therapy index which gives a quantitative measure of the response to treatment This paper describes our method We illustrate its application by comparing two antithyroid drugs, methylthiouracil and potassium perchlorate

Material and Methods

We first studied 40 thyrotoxic patients with diffusely enlarged thyroid glands and exophthalmos—that is to say, they formed a homogeneous group exhibiting classical Graves' disease

All were admitted to hospital and the diagnosis was confirmed by radioactive-iodine studies, including the 4-hour uptake of ^{131}I and the 48-hour plasma-protein-bound radioactivity B.M.R.s and serum-cholesterol values were also estimated.

The patients were allocated to two groups, one to be given methylthiouracil and the other potassium perchlorate Methylthiouracil was given in the doses we use routinely—namely, 200 mg three times a day for two weeks, followed by 100 mg three times a day Potassium perchlorate was given in a dose of 200 mg three times a day which is the dose originally used by Godley and Stanbury (1954)

Before treatment began, the patients were discharged from hospital and instructed to attend weekly At the first outpatient attendance they were examined by a standard routine Each subject was weighed in her clothes and asked to wear the same clothing on subsequent visits She was then instructed to lie down on an examination couch and was left undisturbed for 10 minutes The resting pulse-rate was counted for 1 minute and the presence or absence of the symptoms and signs shown in table I was recorded The history was taken and the physical examination was carried out in the same way for each patient, the criteria for the identification of symptoms and signs being those laid down by Crooks et al (1959), except in the case of the pulse-rate where a resting rate higher than 85 beats per minute was scored as abnormal Throughout the series all observations, with a few exceptions, were made by one of us (J C), whose observations in previous observer-variation studies involving the clinical features shown in table I did not differ significantly from those of 7 other experienced observers (Crooks et al. 1959)

Numerical values were allocated to each clinical feature (table I) on the basis of their diagnostic significance (Crooks et al. 1959) except in the case of appetite increase and weight loss We had previously established that the combination of these two symptoms was of great diagnostic importance, and for the purpose of diagnosis each was rated +3 giving a value of +6 if both were present In the assessment of therapeutic response, however, the restoration of weight loss is of much greater significance than the return of the appetite to normal, and for this reason the rating for the symptom of weight loss was increased to +4 and that for increase of appetite reduced to +1 By adding the values obtained after the first outpatient

TABLE I—WEIGHTING FACTORS ALLOCATED TO THE SYMPTOMS AND SIGNS OF THYROTOXICOSIS

Thyrotoxicosis-therapy index

Symptoms	Score	Signs	Score

* Taken nearest to week in which the patient reached a therapy index of 5 or less

attendance a total score, which we term the therapy index was derived for each patient

At the first outpatient visit treatment began and alternate patients were given methylthiouracil or potassium perchlorate. The patients receiving potassium perchlorate were instructed not to eat fish or iodised salt and to avoid medicines containing iodine

At each subsequent weekly visit the procedure for ascertaining body-weight, resting pulse-rate, and the presence or absence of the clinical features of the disease was repeated. When a symptom or sign disappeared completely its value was deducted from the therapy index of the previous week In the case of weight increase one point was deducted from the initial index for each 4 lb. of weight gained In this way a fresh index was calculated weekly for each patient B.M.R. estimations were carried out in all patients at two-weekly intervals. The technique used was that described by Crooks et al (1958).

Complete remission of the disease or "cure" was taken to have occurred when the therapy index reached and remained within the range 0–5 for three successive weeks The actual week of "cure" was chosen as that week with the lowest of the 3 values. This range was adopted since indices greater than 5 are obtained if two clinical features conventionally regarded as of high diagnostic significance are present simultaneously (table I). Strong confirmation that the range 0–5 indicates full control of the disease was afforded by the estimations of the B.M.R. (table II). Further confirmation was obtained by the observation that in patients who were satisfactorily controlled by antithyroid drugs, indices fluctuated within this range for long periods.

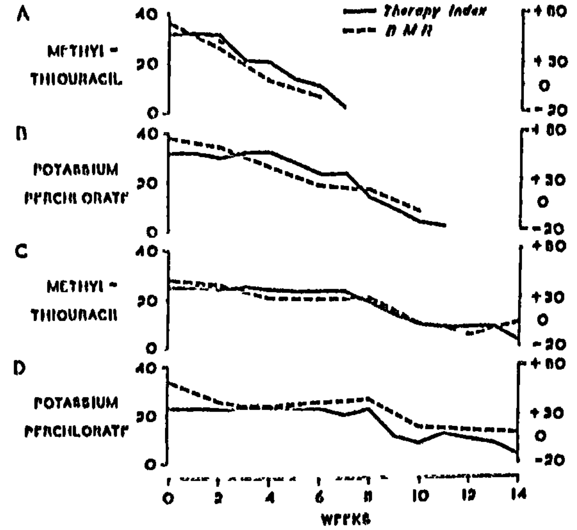

Fig 1—Rate of change in the therapy index and the B.M.R. during treatment with methylthiouracil and potassium perchlorate (600 mg. daily) A and B show linear changes of the therapy indices with time B and C show the delayed type of therapeutic response

When the patient was euthyroid she was given maintenance doses of the drugs ranging from 50 to 150 mg. daily for methyl thiouracil, and 200 to 400 mg. daily for potassium perchlorate After 3 months maintenance therapy administration of the drugs was stopped 14 of the 40 cases (series 1) relapsed and then formed a separate group (series 2). In this investigation patients acted as their own controls The design was similar to that of the "cross-over" method used by pharmacologists for the biological assay of substances such as insulin Thus 8 subjects of series 1 who had been given methylthiouracil, and who had relapsed when therapy was stopped, were retreated with potassium perchlorate. Similarly 6 subjects who had been treated with potassium perchlorate were retreated with methyl thiouracil. The same dosage schemes for each drug were used in retreatment as in the initial treatment and the follow-up procedure was identical Progress was checked by repeated estimations of the B M R

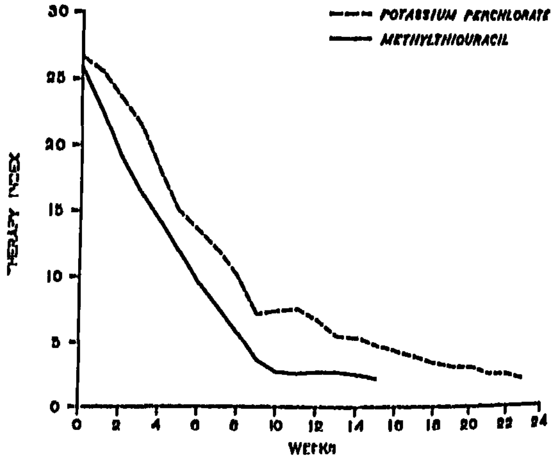

Fig. 2—Rate of change of the mean therapy index produced by potassium perchlorate and methylthiouracil in 2 groups of 20 patients (series 1)

Results

Series 1 (Time taken to "cure")

The number of patients reaching the level we have defined as "cure" at any given time is shown in table III. The mean time to "cure" of the 20 patients receiving methylthiouracil was 9.1 weeks, and the comparable figure for the 20 patients receiving potassium perchlorate was 13.1 weeks These values are significantly different ($P < 0.01$) It can be seen from table III that in the group of patients receiving potassium perchlorate the longest time taken to effect "cure" was 23 weeks compared with 15 weeks for methylthiouracil It also shows the larger number of patients receiving perchlorate who required long courses before "cure" was achieved

Variations of Therapy Index with Time

Typical examples of the changes in the index during therapy are shown in figs 1A (methylthiouracil) and B (potassium perchlorate) The associated changes in the basal metabolic rate plotted on the same figures show good agreement with the clinical method of assessment

TABLE III—DISTRIBUTION OF PATIENTS IN SERIES 1 RECEIVING METHYLTHIOURACIL AND POTASSIUM PERCHLORATE (600 mg DAILY) SHOWING TIME TAKEN TO EFFECT " CURE "

Time to effect " cure " (weeks)	Methylthiouracil (no of patients)	Potassium perchlorate (600 mg daily) (no of patients)
3–4	1	
5–6	3	
7–8	4	5
9–10	10	3
11–12	1	4
13–14		3
15–16	1	
17–18		2
19–20		1
21–22		1
23–24		1
Total	20	20
Mean time to " cure "	9 1 weeks	13 1 weeks

In the case of both patients illustrated in these figures linear regressions of the therapy indices on time showed a significant fall in the values of the index with time This relationship was found to hold in 17 of the 20 patients treated with methylthiouracil The remaining 3 patients were slow to respond to the drug, and the changes both in the therapy index and in the basal metabolic rate in this type of response are shown in fig. 1c. The indices of all 3 patients, however, reached values of 5 or less in subsequent weeks Of the 20 patients treated with potassium perchlorate, 16 showed falls in the value of the index with time which were significant. In 1 of the remaining 4 patients the values of the index suggested that the reason for the non-significant fall was the absence of data on three occasions on which she defaulted. The remaining 3 patients did not respond to treatment until 6 weeks or more had elapsed and an example of this type of response to perchlorate is shown in fig 1D

Fig 2 shows the changes in the mean therapy index with time for each group of 20 patients The more rapid improvement in patients treated with methylthiouracil as compared with potassium perchlorate is clearly seen This method of comparing the effectiveness of the two drugs is, however, statistically unsatisfactory because of the two types of therapeutic response obtained with each drug For example the mean curves for both drugs show a uniform decrease in the value of the index for the first few weeks of treatment and the variations of the type shown in fig 1c and D are concealed It was for this reason that we did not compare the effectiveness of the drugs by the rate of change of the therapy index but adopted the time taken to effect " cure " as the criterion of therapeutic response

Effect of Initial Values of the Therapy Index

A comparison between the initial values of the therapy indices and the times taken to effect " cure " showed that for the groups on either drug there was no significant correlation between these two variables In other words, the time taken to effect " cure " was uninfluenced by the initial degree of severity of the disease

Basal Metabolic Rate

The mean values of B.M.R.s in the patients of both groups of series 1 before and after therapy are shown in table II These do not exactly correspond to the times when the patients had reached the week of " cure " The reason for this discrepancy is that the values of B.M.R.s were obtained at fortnightly intervals, whereas the therapy indices were obtained at weekly intervals For the 20 patients treated with methylthiouracil the mean value after therapy of −3 9 corresponds to a time 0 55 week before the week of " cure ", for the 20 patients on potassium perchlorate the mean value after therapy of 0 0 corresponds to a time 0 35 week before the week of " cure " 2 patients who received potassium perchlorate had B.M.R.s below the usually accepted upper limit of the normal range but were thyrotoxic by all other criteria, including radioactive-iodine tests We have previously pointed out that this may occur and that in such cases the B.M.R. falls with treatment (Crooks et al 1958)

At the beginning of treatment using methylthiouracil the mean value of the B.M.R.s for the 20 patients was +47 0, at the conclusion or rather at 0 55 week before " cure " the mean value was −3 9 with a standard deviation of 9 2 A normal group of individuals would be expected to have a B.M.R. whose mean value is 0 and standard deviation 7 5 approximately Since the mean value of −3 9 is not significantly different from 0 (0 5<P<0 10), the 20 patients had attained the euthyroid state as assessed by the B.M.R. criterion. At the beginning of treatment using potassium perchlorate the mean of the initial readings of B.M.R.s for the 20 patients was +35 7, at the conclusion or rather at 0 35 week before " cure " the mean value was 0 0, with a standard deviation of 10 6 Thus once again the

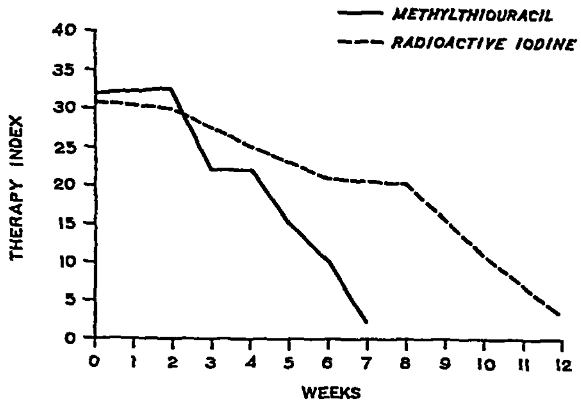

Fig 3—Rate of change of the therapy index produced by methylthiouracil and by radioactive iodine

TABLE IV—TIMES TAKEN TO EFFECT " CURE " IN PATIENTS WHO RELAPSED AFTER TREATMENT SERIES 2

Patient no	Time to effect " cure " (weeks)		Difference (weeks)	Patient no	Time to effect " cure " (weeks)		Difference (weeks)
	Methylthiouracil initial therapy	Potassium perchlorate retreatment			Potassium perchlorate initial therapy	Methylthiouracil retreatment	
21	9	12	−3	7	18	10	+8
22	10	10	0	9	14	7	+7
23	9	22	−13	10	11	9	+2
24	11	9	+2	11	7	4	+3
25	15	22	−7	13	13	14	−1
26	10	12	−2	14	9	4	+5
27	7	16	−9				
33	6	6	0				
Mean time to cure	9 6	13·6	−4 0		12·0	8 0	+4 0

estimation of the B.M.R. confirmed that patients had attained the euthyroid state.

Series 2 (" Cross-over " Observations)

In series 2 the time taken to effect " cure " in 8 subjects who initially received methylthiouracil and who, after recurrence of the disease were given potassium perchlorate, are shown in table IV. " Cure " was also confirmed by B.M.R. estimations in this group of subjects.

A t-test shows that the difference of 4 weeks is not significantly different from zero ($t = -2.18$, $0.05 < P < 0.10$). It should, however, be noted that the difference found—i.e., that potassium perchlorate took 4 weeks longer than methylthiouracil for " cure " to be obtained in the same patients—is similar to the difference found in series 1 in which different patients were given the two drugs. In 6 subjects who had received potassium perchlorate and who were given methylthiouracil after recurrence of the disease, the times to " cure ", confirmed by B.M.R.s, are also shown in table IV. A t-test shows that in this group of subjects the difference of 4 weeks is significantly different from zero ($t = -2.93$, $P < 0.05$). Again the slower rate of control by perchlorate is similar to that obtained between the two groups of 20 patients in series 1.

The findings in these two " cross-over " tests show that it does not matter which drug is given first. It is valid therefore to consider both " cross-over " tests together and to conclude that in this group of 14 subjects potassium perchlorate in the doses used took 4 weeks longer than methylthiouracil to control the disease. These observations confirm the results of series 1 and provide evidence that the method of assessment is reproducible. They also show that the " cross-over " type of control is unnecessary and that no fallacy has arisen from the method of using alternate cases for the two drugs.

Comparison of the Response to Antithyroid Drugs and Radioactive Iodine

The therapy index can be used to compare the response to antithyroid drugs with other forms of treatment—e.g., radioactive iodine. Fig. 3 illustrates the rate of response in one patient treated with 7 mC of radioactive iodine compared with the patient shown in fig. 1A treated with methylthiouracil. We are now using the method to study the therapeutic response of a group of patients who have been treated with radioactive iodine.

Discussion

There are many advantages in being able to follow quantitatively the degree of improvement which results from therapeutic procedures, and the purely clinical method we describe here makes it possible to obtain more consistent estimates of a patient's progress than when conventional methods are used. Thus when it is necessary for the same patient to be seen from time to time by different clinicians, our system of scoring tends to eliminate personal bias in the interpretation of the observations. The proforma also acts as an aide-memoire enabling facts to be recorded and analysed quickly. It should be stressed that in systems of this type it is necessary to use a standard method of history-taking and to adopt rigid criteria for the recognition of physical signs. Used as a method of scientific investigation our scheme enables statistical methods to be applied to the results of treatment. In the present study for example, it has enabled us to show that the usual therapeutic response to antithyroid drugs is linear with time. It has also brought out the absence of any relationship between the initial severity of the disease and the rate of therapeutic response.

We feel, however, that the main value of this method of assessment is to provide a more accurate method of comparing the therapeutic effectiveness of different antithyroid compounds. There are comparatively few ways in which this can be done. In animals, methods depending on their goitrogenic action have been devised using either the immature rate (Astwood et al. 1945) or the chick (VanderLaan and Bissell 1946). In man, Stanley and Astwood (1947) have shown that the property which some antithyroid drugs possess of inhibiting the uptake of radioactive iodine can be utilised to give a measure of their relative potencies. Though this technique has the great merit that the comparison is made in the human subject, it is known that the results are not necessarily applicable to a patient suffering from thyrotoxicosis. Moreover, it is valid only when applied to drugs which act at the same point on the chain of thyroid-hormone synthesis and so cannot be used to compare the activity of drugs such as potassium perchlorate with the thiouracils and imidazoles since the former act on the iodide-trapping mechanism whereas the latter affect the conversion of iodide to organically bound iodine.

Drugs should, if possible, be assayed on patients suffering from the disease for which they are to be used, so that the pharmacological mechanisms underlying their effect becomes relatively unimportant. For this reason we believe that the ratio between the effectiveness of methylthiouracil and potassium perchlorate in the doses we chose is the most accurate figure so far recorded. It is of great interest, and provides strong confirmatory evidence of the validity of our method, that an almost identical difference in activity was shown in two separate experiments of different design. In both series of cases the conclusions were confirmed by estimation of B.M.R. In the second series each patient acted as her own control and the method used is an application to man of the " cross-over " tests used in animals by experimental pharmacologists. So far as we know this is the first example of the use of this particular technique in human pharmacological investigations. There are, of course, few conditions in which it is permissible to stop the administration of an effective drug and to allow the patient to relapse before using a second form of treatment. These observations also showed that the order of administration of the two antithyroid drugs did not affect the final result.

We believe that this scoring system of assessing therapeutic response in thyrotoxicosis is widely applicable. We have described in this paper how it can be used to compare the activities of two antithyroid drugs. The doses we used were those which we were using when the tests were begun, and the results indicate that, weight for weight, methylthiouracil is more potent than potassium perchlorate. Further observations, which will be the subject of a separate communication, show that this is a question of dosage, and that in higher doses potassium perchlorate is an equally effective form of treatment.

Summary

A clinical method of comparing the relative effectiveness of therapeutic procedures in thyrotoxicosis is described. It is based on the allocation of numerical values to those features of thyrotoxicosis which can be reversed by treatment. The sum of these values is called the therapy index and can be used to assess the progress of an individual case. We illustrate its use in the comparison of two antithyroid drugs. Thus therapy indices were recorded weekly in two groups of 20 cases, one group receiving methyl-

thiouracil and the other potassium perchlorate The antithyroid activity of both drugs was assessed by the time taken for the index to fall within the range 0 to 5 Estimations of the basal metabolic-rate confirmed that at this level patients were euthyroid The time taken to reach the euthyroid state was independent of the initial severity of the disease In 33 of 40 patients the rate of therapeutic response bore a linear relationship to time Methylthiouracil in doses of 600 mg a day for three weeks followed by doses of 300 mg a day was shown to be a more effective antithyroid drug than potassium perchlorate in doses of 600 mg a day A " cross-over " test carried out on 14 patients, who had relapsed after a first course of treatment, confirmed this conclusion

At some time during the course of their disease the majority of patients with thyrotoxicosis receive an antithyroid drug It is probable that these substances provide the most satisfactory form of treatment for most young patients and the speed and certainty of their action often make their immediate administration necessary even when it has been decided subsequently to use an alternative form of treatment It is obviously of importance to know which is the most effective and the safest member of the group The ideal antithyroid drug should be rapid in its action and should produce no adverse side-effects In this country the two most commonly used drugs are methylthiouracil and carbimazole In other countries propylthiouracil and methimazole are popular All, however, occasionally produce toxic effects, of which agranulocytosis is the most serious since it may prove fatal The most common adverse reaction is the drug rash, but nausea, drug fever, aplastic anæmia, thrombocytopenia, conjunctivitis, and lymph-gland enlargement have all been reported

Methylthiouracil was first introduced in 1944 and was for long the standard antithyroid substance in use in this country Carbimazole received favourable reports in 1953 from Doniach and from Poate It was said to produce fewer side-effects than methylthiouracil although its action was slower Its use has tended to increase especially since evidence that it is less toxic was produced by Greene and Morgan (1956) and by Burrell et al (1956) It is said to be ten times as active as methylthiouracil and is usually given in one-tenth of the dose The *British Pharmacopœia* recommends that the controlling dose of methylthiouracil should be from 0 2 to 0 6 g daily and of carbimazole from 30 to 60 mg daily

Potassium perchlorate is a rival and more recent antithyroid drug with a different type of action Unlike the thiouracils and imidazoles which prevent the iodination of tyrosine, it acts by inhibiting the iodide-trapping mechanism of the thyroid gland As a simple inorganic compound it would seem a priori to be less likely to produce sensitisation effects than the organic antithyroid substances, and in particular to be less likely to damage the hæmopoietic system It was first shown to be a suitable substance for clinical use by Godley and Stanbury (1954) This was confirmed in a much larger series of cases by Morgans and Trotter (1954) who found that the rate of response produced by 400 mg daily was less than that produced by methylthiouracil in a dose of 200 mg daily

Shortly after their report was published we decided to assess the relative merits of potassium perchlorate, methylthiouracil, and carbimazole We shall present our conclusions based on a study of more than 450 patients It soon, however, became evident that while the comparative incidence of the side-effects of these substances would be revealed by this investigation a comparison of their relative efficacy presented a more difficult problem For this reason we devised a clinical method of comparing antithyroid drugs based on the allocation of points to those features of thyrotoxicosis which are reversible by therapeutic measures This enabled us to derive a " therapy index " which could be followed from week to week and the time taken for it to reach and remain at a value of 5 or lower could be used as a measure of the effectiveness of the form of treatment. We have already recorded in illustration of our method a comparison of the effect of 600 mg daily of potassium perchlorate with that of methylthiouracil in doses of 600 mg daily for two weeks followed by 300 mg daily Using these dosage schemes methylthiouracil was more effective (Crooks et al 1960) It seemed to us probable that this result depended on the relative doses used and a further series of cases has been studied using 1000 mg of potassium perchlorate daily Since our clinical experience had led us to doubt the statement that carbimazole is, weight for weight, ten times as active as methylthiouracil we also compared these two substances

Potassium perchlorate proved to be both effective and relatively free from side-effects and we now use it routinely We have, therefore, studied more closely some of its alleged disadvantages notably the tendency for its activity to be affected by variations in the dietary intake of iodine and its liability when used before operation to produce an unduly vascular gland We also report the results of its use in pregnant patients with thyrotoxicosis

Material and Methods

We have studied two further groups of 20 cases in addition to the two already reported (Crooks et al 1960)

All the patients had diffuse goitres and exophthalmos and thus were examples of classical Graves's disease To one group carbimazole was given in doses of 20 mg three times a day for two weeks followed by 10 mg three times a day (i e , one-tenth of the dose of methylthiouracil which was used in our previous series) Potassium perchlorate was given to the other group in a dose of 200 mg 5 times a day The dietary intake of iodide was not restricted

The method of comparison was that used in the earlier series except that estimations of basal metabolic-rate (B M R) were made only at the end of the investigation to confirm that the patients were euthyroid

TABLE I—DISTRIBUTION OF PATIENTS IN SERIES 3 RECEIVING CARBIMAZOLE AND POTASSIUM PERCHLORATE (1000 MG DAILY) SHOWING TIME TAKEN TO EFFECT " CURE "

Time to effect " cure " (weeks)	Carbimazole (no of patients)	Potassium perchlorate (1000 mg daily) (no of patients)
3–4		
5–6		8
7–8	7	3
9–10	2	4
11–12	4	1
13–14	3	2
15–16		1
17–18	2	
19–20		1
21–22	2	
Total	20	20
Mean time to " cure "	12 3 weeks	9·4 weeks

The study of the comparative toxic effects of these substances is based on observations made on 486 patients seen and treated by us in our wards or clinic After reference to their general practitioner they continued to attend hospital from time to time so that the occurrence of toxic effects could be accurately recorded

Results

" *Therapy Indices* "

The times taken to effect " cure " for both drugs are shown in table I The mean time to " cure " of the 20 patients on carbimazole was 12 3 weeks and the corresponding figure for potassium perchlorate was 9 4 weeks

Table II gives the mean times to " cure " of the groups treated with methylthiouracil, carbimazole, and potassium perchlorate in doses of both 600 mg and 1000 mg daily

For the purpose of statistical analysis the drugs have been represented by the letters A, B, C, and D as shown in the table An analysis of variance on the 80 patients studied shows that there are significant differences between the mean values for A, B, C, and D In particular A is significantly different from B and C ($P < 0.05$), D is significantly different from B and C ($P < 0.05$), and there was no significant difference between A and D A further analysis of variance was carried out on the 60 patients remaining after the exclusion of those who had been given methylthiouracil It was found that there was a significant difference between B and D ($P < 0.05$), a significant difference between C and D ($P < 0.05$), and no significant difference between B and C

TABLE II—MEAN TIMES TO EFFECT " CURE " FOR METHYLTHIOURACIL, POTASSIUM PERCHLORATE, AND CARBIMAZONE

Drug	Time to effect " cure " (weeks)
A Methylthiouracil	9 1
B Potassium perchlorate (600 mg daily)	13 1
C Carbimazole	12 3
D Potassium perchlorate (1000 mg daily)	9·4

These results can be summarised as follows methylthiouracil in doses of 600 mg daily for 2 weeks followed by 300 mg daily and potassium perchlorate (1000 mg daily) were equally effective as measured by the time taken to effect " cure ", while both were more effective than carbimazole in one-tenth of the dose of methylthiouracil or potassium perchlorate (600 mg daily)

Effect of Variations in the Intake of Iodine on Potassium Perchlorate Therapy

Potassium perchlorate affects the iodide-trapping mechanism of the thyroid and it is known that the goitrogenic action of substances with this action can be overcome if sufficient iodide is given (Franklin et al 1944) In our earlier series we advised patients given potassium perchlorate 600 mg daily, to restrict their iodine intake by excluding fish from the diet, by using uniodised salt, and by avoiding medicines

Diet histories from 8 patients and urinary assays from 20 patients revealed a great variation in the degree to which iodide restriction had been achieved The therapeutic responses to potassium perchlorate of patients with relatively high and low intakes were statistically analysed and no difference was found In our later observations therefore we have urged no dietetic restrictions and have merely advised patients to avoid certain cough medicines which contain iodide in relatively large quantities

Preoperative Use of Potassium Perchlorate

It is generally agreed that antithyroid drugs should be used to prepare a thyrotoxic patient for partial thyroidectomy The usual method is to bring the disease under control with one of the organic antithyroid drugs and then to give iodide for 10–14 days before operation It is said that this renders the gland less vascular and diminishes the likelihood of postoperative thyroid crises

Godley and Stanbury (1954) prepared 13 patients for operation with potassium perchlorate and stated that the consensus of opinion of the operating surgeons was that a few of the glands were more vascular than those of patients prepared with propylthiouracil and iodine 2 patients who before operation received iodide in addition to perchlorate escaped from control For this reason Morgans and Trotter (1954) did not use perchlorate in those patients who were likely to require partial thyroidectomy

We have prepared 20 patients for operation with potassium perchlorate alone 18 of these patients had small nodular glands and the surgeon did not find more technical difficulty due to increased vascularity of the gland than after conventional preparation

Opinions as to the degree of vascularity must of necessity be highly subjective It may well be that contradictory views on the effects of the antithyroid drugs on vascularity are due to variation in the selection of cases and to the lack of an investigation designed so as to eliminate the effects both of biological variation and of bias on the part of the surgeon The blocking effect of potassium perchlorate on thyroid hormone synthesis continues for some time after the drug has been withdrawn and administration can cease at the time of operation

Use of Potassium Perchlorate During Pregnancy

Opinion is almost unanimous that the most appropriate form of therapy for women who develop thyrotoxicosis during pregnancy is the administration of an antithyroid drug Goitre and hypothyroidism have been reported in the infants of mothers who have received these substances but it is rare, and when it occurs the dosage has almost always been unduly high (Macgregor and Goodwin 1953) We have treated 12 pregnant thyrotoxic patients with potassium perchlorate and in each have achieved satisfactory control of the disease One of the infants had a very slight enlargement of the thyroid gland which disappeared within 6 weeks The remainder showed no abnormality of any kind We report these results to show that the different mode of action of potassium perchlorate and its special physical properties do not render it more liable to affect the fœtal thyroid than the antithyroid substances in more common use

Toxic Effects of Antithyroid Drugs

We have treated 486 patients with either methylthiouracil, carbimazole, or potassium perchlorate for sufficiently long to be able to assess their relative tendency to give rise to toxic side effects Table III shows our results No statistically significant difference was found

TABLE III—TOXIC EFFECTS

Toxic effect	Methylthiouracil (600 mg daily 2 wks, then 300 mg daily)	Carbimazole (60 mg daily 2 wks, then 30 mg daily)	Potassium perchlorate	
			600 mg * or 1000 mg	1500 mg † or 2000 mg
No of cases	151	85	200	50
Skin rashes	5	4	1	5
Nausea		1	3	2
Drug fever	2			
Agranulocytosis	2	2		1
Thrombocytopenia	1			

* 35 patients † 10 patients

between the liability of the organic substances to produce sensitisation reactions such as skin rashes or blood dyscrasias Potassium perchlorate, on the other hand, in doses of 1000 mg a day or under was less likely than the organic antithyroid compounds to produce adverse effects of this type Higher doses of potassium perchlorate produced reactions as frequently as the organic compounds

The rashes produced by potassium perchlorate were maculopapular and were confined to the extremities except in 1 patient in whom the rash was generalised This patient had an associated pyrexia and marked desquamation followed the disappearance of the eruption. In 3 of the 6 cases the rash subsided although the administration of the drug was continued.

The patient with agranulocytosis was a young woman receiving 1500 mg of potassium perchlorate a day During the third week of treatment she developed a sore throat, pyrexia, and generalised muscular pain. Blood examination showed a total polymorphonuclear leucocyte count of 750 per c.mm The peripheral blood was otherwise normal and the bone-marrow showed no evidence of a maturation defect of the white-cell series Administration of the drug was stopped and the leucocyte count rose rapidly to normal levels The patient had received no other drugs which might have caused leucopenia.

The rashes produced by the organic antithyroid compounds were all maculopapular This is a type of eruption which is well known to occur in those who become sensitised to this series of compounds Urticaria which has also been reported was not observed in this series

4 patients complained of nausea while taking potassium perchlorate. 3 of them were able to continue taking the drug when an antacid mixture was given along with it and the nausea disappeared within a week. The fourth refused further treatment.

Discussion

The "therapy index" has been used to assess the rate of improvement in four different groups of patients suffering from classical Graves' disease One group received carbimazole, one methylthiouracil, and the other groups potassium perchlorate in two different doses From these investigations we are able to draw two conclusions First, carbimazole is less effective than methylthiouracil when given in one-tenth of the dose Secondly, potassium perchlorate is more effective in high than in low dosage

The very extensive literature on the antithyroid drugs is fully reviewed by McGavack (1951), Werner (1955), and Crooks (1957), and it is clear that the four drugs most widely used at present are methylthiouracil, propylthiouracil, methimazole, and carbimazole All are effective and relatively safe The particular substance used by any given physician seems to be determined by two factors In the first place it is clear that the country of origin is important since methylthiouracil and carbimazole were both first synthesised and marketed in Europe whereas propylthiouracil and methimazole were originally American products The second factor of importance is the relative conservatism of the individual clinician. Most physicians see no reason to try a new remedy if the existing one is satisfactory although some are impressed by new substances even if their advantages are marginal Moreover, any clinician tends to be overimpressed by an example of a patient under his care who shows a serious side-effect even though the statistical hazards of this occurrence can be shown to be small Against this background of national and individual prejudice there is almost no statement which has not been made about the relative effectiveness, speed of action, and toxicity of these drugs

We have found no published observations on the relative dosage of antithyroid drugs which cannot be explained on the view that the response of a patient to an antithyroid drug is a function of the dose At a certain critical level a dose is reached at which synthesis of the thyroid hormone is completely blocked Inspection of curves showing the effect of different doses of methylthiouracil on the uptake of radioactive iodine by the gland, as reported, for example, by Goodwin et al (1949), illustrate this phenomenon

The first problem in dealing with the dose of an antithyroid drug is to discover the least dose which in the majority of patients will effectively block secretion of the thyroid hormone during each 24 hours This is probably of the order of 450 mg for methylthiouracil, 60 mg for carbimazole, and 1000 mg for potassium perchlorate The question then arises of the relative liability of these drugs to produce toxic side-effects In spite of their importance we know relatively little about sensitisation reactions to drugs It is not possible, for example, to say with certainty whether they are dependent on dose. With some drugs (e g , amidopyrine) a single dose may produce a reaction in a sensitised patient With others, such as chloramphenicol or the sulphonamides, there seems to be a tendency for reactions to be related to total dosage In the case of the antithyroid substances the balance of evidence seems to suggest that they belong to the latter type (Lehr 1948) Certainly our own results show that potassium perchlorate produces more reactions in high than in low dosage. It seems therefore to us that it is unjustifiable to group together series of cases collected from the literature without allowing for this factor of dosage and without applying statistical tests of significance to all the results reported The two published comparisons of carbimazole and methylthiouracil (Burrell et al 1956, Greene and Morgan 1956) are thus rendered inconclusive

Our tentative conclusions are these There is no convincing evidence that any of the organic antithyroid drugs is significantly more toxic than any other when it is given in therapeutically equivalent dosage Our experience suggests that potassium perchlorate is less liable to give rise to skin rashes or blood dyscrasias in doses which act as quickly as the conventional therapeutic doses of methylthiouracil and carbimazole.

Potassium perchlorate thus appears to us to be the antithyroid drug of choice A few observers other than Godley and Stanbury (1954) and Morgans and Trotter (1954) have used it and found it satisfactory Thus Kleinsorg and Kruskemper (1957) treated 47 cases with doses of 1 6 to 2 0 g a day, 2 patients developed a rash Buttaro and Brunori (1955) reported 25 patients successfully treated with doses of 600 mg a day and 1 developed a skin rash Observations in our series showed that it is unnecessary to restrict the dietetic intake of iodine during the administration of potassium perchlorate In our experience this drug can be satisfactorily used for preoperative preparation when the gland is small and nodular Whether or not it can be used in this way when the gland is large requires further investigation

Sensitisation to potassium perchlorate can occur The usual manifestation is a rash which usually subsides quickly even if administration is continued It is much more likely to develop when the dosage is high Our single case of agranulocytosis occurred in a patient receiving large doses of the drug but if the use of potassium perchlorate increases we should not be surprised to learn that this serious condition may be associated with lower doses or that the bone-marrow may be affected in other ways The balance of present evidence, however, is in favour of its very low toxicity It has the additional merit of being very cheap and it is of some interest that the only proprietary preparation of potassium perchlorate was for many years in category 5 of the List of Proprietary Medicines Classified by the Joint Committee on Prescribing which is published jointly by the Ministry of Health and the Department of Health for Scotland

Summary

A clinical method of assessing the rate of improvement of groups of patients suffering from thyrotoxicosis has been applied to four series of cases receiving respectively methylthiouracil, carbimazole, and potassium perchlorate in two different doses Carbimazole was less effective than methylthiouracil when given in one-tenth of the dose Potassium perchlorate in high dosage was as effective as methylthiouracil and more effective than carbimazole and smaller doses of perchlorate

Four larger series of patients receiving these drugs were studied to ascertain the incidence of toxic side-effects Potassium perchlorate in a daily dose of 600–1000 mg produced fewer side-effects than when it was given in daily doses of 1 5–2 0 g The lower dosage range also gave rise to fewer side-effects than either methylthiouracil or carbimazole in therapeutically equivalent doses No statistical difference in the incidence of sensitisation reactions was found between the latter two substances

Potassium perchlorate in high doses is liable to produce skin rashes, and in 1 of our cases agranulocytosis developed

It is not necessary to restrict the dietary intake of iodine during perchlorate administration It can be used to prepare patients for thyroidectomy when the gland is small and nodular and can also be used during pregnancy Potassium perchlorate, 1000 mg daily in divided doses, is the antithyroid drug of choice in the medical treatment of thyrotoxicosis

We wish to thank Dr R A Robb, Mitchell lecturer in statistics, University of Glasgow, for help with the statistical aspects of this work, and Mr D H Clark, F R C S , who carried out the thyroidectomies to which we refer

THE INCREASE IN DIFFUSING CAPACITY OF THE LUNGS ON EXERCISE

AN EXPERIMENTAL AND CLINICAL STUDY

J MacNamara
M D N U I , M R C P

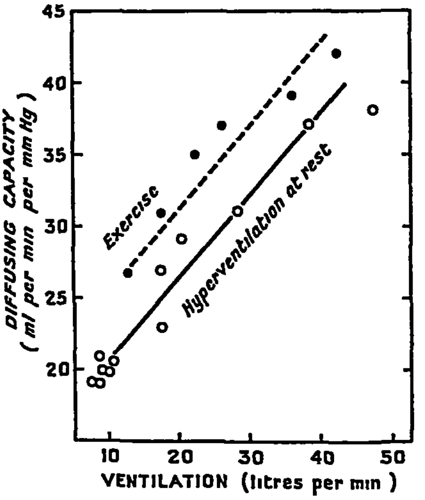
When oxygen is taken up from the alveoli of the lungs it has to penetrate the mechanical barrier of the tissue elements and fluids separating it from the molecules of hæmoglobin in the red cells, the process is one of simple physical diffusion Methods of measuring the permeability of this barrier to gases have been elaborated which permit an estimate of the so-called *diffusing capacity* of the lungs The simplest of these uses carbon monoxide as the test gas, and measures its rate of absorption in the steady state (Bates, Boucot, and Dormer 1955) The measured rate of uptake of this gas in low concentration in an inspired gas mixture is divided by its mean alveolar concentration during the test (expressed as partial pressure) to give a result in ml per min per mm Hg. On physical principles, it may be assumed that the diffusing capacity thus measured is proportional to the area of the diffusing surface and varies inversely with its thickness Normal results vary between 15 and 25 ml per min per mm Hg at rest and from 25 to 40 ml during exercise Experience in the past few years in many centres has shown how valuable measurements of diffusing capacity are clinically, moreover, many facts of physiological interest and importance have been revealed by them Among the latter is the observation, repeatedly confirmed, that the diffusing capacity is greatly increased during exercise The object of this communication is to report some investigations which throw light on the way in which this change is brought about

Investigations and Conclusions

In an experimental assessment of the steady-state method of measuring pulmonary diffusing capacity using carbon monoxide (MacNamara, Prime, and Sinclair 1959) we drew attention to the fact that the results obtained were significantly dependent on the minute-volume of respiration during the test This finding made us wonder whether the apparent increase in diffusing capacity on exercise was due entirely to the effects of hyperventilation. We therefore measured the diffusing capacity in four healthy subjects at rest during voluntary hyperventilation at various rates We found that the diffusing capacity rose steadily with increasing ventilation, showing no definite tendency to a maximum value within the range of voluntary hyperventilation which it was possible to maintain for the time required for the test These results were compared with values of diffusing capacity in the same subjects, measured at various rates of exercise, by plotting both sets of values on a graph relating them to pulmonary ventilation Contrary to our expectation, we found that the curves plotted from the exercise values did not coincide with those for voluntary hyperventilation but lay above them A typical comparison in one subject is shown in the figure This discovery has since been confirmed by results published by two groups working independently in America (Ross, Frayser, and Hickham 1958, and Turino, Brandfonbrener, and Fishman 1959)

We concluded that some factor other than hyperventilation contributed to the increase occurring during exercise and that this was most likely to be the consequence of the increased pulmonary blood-flow Before proceeding further we excluded, by suitable experiments, the possibility that our findings were the result of sampling errors or changes in mean lung volumes (see appendix) We then considered how best to assess the effects of increasing pulmonary blood-flow and decided as a first step to measure diffusing capacity in a number of patients with congenital heart-disease without pulmonary hypertension, in whom pulmonary blood-flow had been measured by cardiac catheterisation and found to be above normal The data collected from these patients are set out in the table We found that in all of them diffusing capacity was above normal at rest, but was not increased beyond normal on moderate exercise, in other words, the range of change observed between rest and exercise was not so great as in normal subjects, although the minute-volume of respiration increased in a normal manner



Plot of values of D_L during hyperventilation at rest (o) and during periods of exercise of differing severity (●) in one subject.

No mention has yet been made of similar findings by other workers Ross et al were unable to demonstrate any increase in diffusing capacity at rest when cardiac output was increased as much as twofold by administration of atropine or noradrenaline to normal subjects, whilst Turino et al failed to find results below normal in subjects with a low cardiac output due to mitral stenosis

PULMONARY DIFFUSING CAPACITY FOR CARBON MONOXIDE (D_L) MEASURED BY THE STEADY-STATE TECHNIQUE AT REST AND DURING EXERCISE IN 10 PATIENTS SUFFERING FROM AURICULAR SEPTAL DEFECT WITH HIGH PULMONARY BLOOD-FLOW (CO) BUT NO INCREASE IN PULMONARY VASCULAR RESISTANCE

Expected values for D_L at rest are shown in parentheses, they are derived from values obtained in healthy subjects of the same height and weight

Patient	Age and sex	Height (in.)	Weight (lb)	Pulmonary ventilation (litres per min)		D_L (ml per min per mm. Hg		CO (l per min) at rest
				Rest	Exercise	Rest	Exercise	
1	14 F			11 2	27 7	25 ( )	29	22
2	15 M	60	99	7 7	22 9	33 (15)	36	15
3	16 M	62	112	9 4	19 6	29 (17)	33	8
4	17 F	68	118	7 1	18·9	28 (20)	33	19
5	18 M	64	113	7 8	20 8	37 (19)	46	14
6	36 M	66	122	6 3	27 5	24 (20)	39	13
7	36 F			10 0	29 0	27 ( )	40	23
8	45 F	64	126	14 0		32 (20)		30
9	46 M	70	140	12 0	28 3	31 (23)	34	22
10	46 M	66	136	9 8	25 6	33 (22)	40	15

The findings described suggest very strongly that the increase in diffusing capacity accompanying exercise is in large part mediated by the hyperventilation that exercise induces Voluntary hyperventilation probably increases the area of the capillary wall separating blood and gas, either by actually distending the pulmonary capillaries with blood or by causing alveoli which are more or less functionless during quiet breathing to become ventilated and perfused The high diffusing capacity observed in the patients suffering from atrial septal defect is likewise due probably to an increase in pulmonary alveolar-capillary blood volume with a consequent increase in area of the interface between blood and gas The most likely reason for the failure to detect any change in diffusing capacity when pulmonary blood-flow is increased by drugs (Ross et al 1958) is that these substances had no effect on pulmonary capillary blood volume, pulmonary blood-flow per se would be expected to have no effect on the rate of carbon-monoxide uptake from the alveolar gas

The possibility should be mentioned that hyperventilation in the absence of exercise may produce values for diffusing capacity which are lower than they should be because a high alveolar oxygen tension depresses the rate of uptake of carbon monoxide by hæmoglobin During hyperventilation at rest alveolar oxygen tension may rise as high as 125 mm Hg which is about 30 mm Hg higher than that found during heavy exercise Calculation from data published by McNeil, Rankin, and Foster (1958) shows that this difference could depress the pulmonary diffusing capacity by about 2 ml per min per mm Hg during voluntary hyperventilation This estimate represents the highest possible effect of the difference in alveolar oxygen tension in these two states, in most of our experiments exercise was not very severe and was not probably accompanied by a fall of alveolar oxygen tension below about 100 mm Hg Thus it is possible that about half the observed difference in level between the results on exercise and those during voluntary hyperventilation may be due to this effect

We therefore conclude that the observed increase in pulmonary diffusing capacity during exercise is due primarily to an increase in the area of capillary wall exposed to alveolar gas This is mediated partly by the hyperventilation itself and partly by the increased cardiac output in exercise

Summary

In patients suffering from atrial septal defect with high pulmonary blood-flow but without pulmonary hypertension the pulmonary diffusing capacity is considerably higher than normal, exercise increases it relatively less than in normal subjects This indicates that the area of blood-gas interface is the important factor underlying the increase in diffusing capacity which occurs in normal subjects during exercise and during voluntary hyperventilation

Appendix

Pulmonary diffusing capacity (D_L) was measured in these experiments by a method similar to that of Bates et al (1955) fully described by MacNamara et al (1959)

1 We excluded errors of sampling as a cause of the increase in D_L observed during voluntary hyperventilation by taking our alveolar samples simultaneously at two points in expiration separated by 450 ml of expired gas When tidal volumes were of the order of 1 litre and over, little difference was found between these samples

2 That the observed change was not solely due to large swings in intrathoracic pressure we confirmed by constricting the airway of the apparatus while the subject maintained a normal rate and depth of breathing This procedure did not alter the value of D_L, although respiratory pressure swings of 40–50 cm of water were induced which are of the same order as those encountered during vigorous hyperventilation with a free airway

3 We carried out the tests with the subjects breathing with their chests voluntarily held above the resting respiratory position so that the volume of gas contained by the lungs at the end of each breath was up to 2l above normal This manœuvre had no effect on the diffusing capacity, confirming Marshall's previous findings (Marshall 1958)

4 Finally we arranged our apparatus so that the subjects hyperventilated against a constant positive pressure of about 15 cm of water, the object of this manœuvre was to drive blood out of the lungs and thus, on our hypothesis outlined above, to prevent or limit the expected increase in D_L This experiment failed to achieve its object, probably because the pressure used was too low, pressures higher than this could not be tolerated long enough for the tests

Our thanks are due to Dr J G Scadding and our laboratory staff who have helped us considerably in the production of this work

TRANSTHORACIC VAGOTOMY FOR STOMAL ULCERATION

CHARLES WELLS
M B Lpool, F R C S
PROFESSOR OF SURGERY, UNIVERSITY OF LIVERPOOL

REUBEN SILBERMAN
M B W'srand, F R C S , F R C S E
LECTURER IN SURGERY IN THE UNIVERSITY

STOMAL ulceration following gastric resection is not common, while stomal ulceration following gastroenterostomy is seen only as an occasional legacy of the past Both these groups of cases can be treated by gastric resection with excision of the ulcer, which may or may not include an abdominal vagotomy Abdominal vagotomy alone, as a planned procedure, may prove very difficult, and, whether it be difficult or easy, the surgeon may be tempted to change his plan and resect an ulcer mass that would be better left alone Transthoracic vagotomy, as the sole procedure, is an alternative which offers certain definite advantages such as technical ease, very low morbidity and mortality rates, and freedom from the sequelæ of extensive excision of the stomach We describe here our results with this procedure

Last April we reviewed all the cases of stomal ulceration seen on the professorial unit at the Liverpool Royal Infirmary between December, 1952, and mid-1957 and treated solely by transthoracic vagotomy All but a few were personally questioned and examined 2 remain untraced (a common experience in a seaport town), leaving for assessment 23 (17 males, 6 females), the youngest of whom was 28 and the oldest 73 at the time of operation

Barium-meal examination had provided definite evidence of ulceration in 12 cases and suggestive evidence in 4 In the remaining 7 there were strong clinical grounds (severe epigastric pain, vomiting and/or bleeding) for the diagnosis of stomal ulceration Gastroscopy was carried out in some cases, but gave little help Fractional test-meal was performed in most cases, provided supportive evidence in 11 where high or average acid levels were found Negative findings in test meals after gastric operations are notoriously unhelpful We have not used the insulin-provoked test meal for gastric acidity after vagotomy Today the twelve-hour overnight secretion would ordinarily be estimated, but this was not done routinely in our series

TABLE I—RESULTS OF TRANSTHORACIC VAGOTOMY FOR STOMAL ULCERATION

Previous operation	No of cases	Failures
1 Gastro-enterostomy	4	0
2 Gastric resection		
Polya	5	0
Steinberg [1]	2	1
Roux-Y	4	1
Billroth I (including modified [2] Billroth I)	5	2
Moroney [3]	3	2

[1] Double-lumen gastrojejunal anastomosis of the " pantaloon " type
[2] End-to-side gastroduodenal anastomosis with wide stoma
[3] Colonic implant between stomach and duodenum with reversed peristalsis

No deaths had resulted from the operation nor any major complications While in hospital some patients had had segmental left-lower-lobe collapse with a small effusion, and for a few months after operation a minority complained of wound pain

Results

The results are summarised in table I

Gastroenterostomy group (4 patients) —The stomal ulceration had developed fourteen to twenty-five years after gastroenterostomy Vagotomy relieved all four patients of their ulcer symptoms and they were well at the time of follow-up

Gastric-resection group (19 patients) —The majority had previously had more than one operation In 13 all symptoms were removed by thoracic vagotomy and 11 of these were well at the time of follow-up The other 2 had died from unrelated causes

The first had developed stomal ulceration after a Steinberg gastrectomy and was relieved by vagotomy, but he died six years later from carcinoma of the bladder The second, whose stomal ulcer followed a Billroth I gastrectomy for gastric ulcer, was also relieved by vagotomy but died of cirrhosis of the liver nine months after the operation

Of the remaining 6 (unrelieved) cases, no fewer than 4 proved to have been badly selected 1 patient, who had had a Roux-Y gastrectomy, was a chronic alcoholic and was afterwards admitted to a mental home The other 3, who had complained of epigastric pain and vomiting, were found at subsequent laparotomy to have no evidence of stomal ulcer, active or healed Their histories are

CASE A (*Steinberg gastrectomy*) —1951 gastropexy elsewhere for partial gastric volvulus 1952 Steinberg gastrectomy for duodenal ulcer and hiatus hernia 1953 transthoracic vagotomy (confirmed histologically) failed to relieve persistent epigastric pain 1958 no ulcer found at laparotomy Converted to " *Moroney* " Since then the attacks of epigastric pain have been less frequent, they seem to have been due to intestinal hurry

CASE B (*modified Billroth I*) —1952 pylorectomy and vagotomy for duodenal ulcer, performed elsewhere 1953 modified Billroth I for persistent duodenal ulcer 1957 transthoracic vagotomy On histological examination, amputation neuromata found Symptoms unrelieved Roux-Y conversion carried out as a last resort but without improvement

CASE C (*Moroney*) —1926 gastroenterostomy 1946–47 Polya gastrectomy for recurrent ulceration Severe nutritional deficiencies followed (anæmia, pellagra, riboflavin deficiency) probably as a result of extreme intestinal hurry (barium was demonstrated in the cæcum an hour after ingestion). 1952 Moroney conversion for intestinal hurry. 1953 transthoracic vagotomy for suspected stomal ulcer. 1956 Roux-Y conversion after excision of colonic implant (no ulcer found). Pain, vomiting, and nutritional deficiencies persist, albeit to a lesser extent. A recent barium meal was negative. Fasting test-meal showed achlorhydria.

In the 2 other patients stomal ulceration continued despite transthoracic vagotomy.

CASE D (*modified Billroth I*).—1953 Modified Billroth I, with abdominal vagotomy for duodenal ulcer. 1955 transthoracic vagotomy for a stomal ulcer (bilateral vagal-nerve section was confirmed on histological examination). 1957 insulin test-meal at blood-sugar 35 mg. per 100 ml. produced 100 clinical units of total acid. Further one-third gastric resection with Polya anastomosis for posterior stomal ulcer. Has since remained very well.

CASE E (*Moroney*).—1949 Polya gastrectomy elsewhere (apparently no ulcer was found). 1952 converted to Moroney for intractable dumping. Abdominal vagotomy 1952. 6th–9th left intercostal nerves crushed for severe epigastric pain, without relief. 1953 transthoracic vagotomy (fractional test-meal showed hyperchlorhydria). Histological proof of bilateral vagotomy obtained. One week after operation, test-meal showed achlorhydria. 1957 radiography revealed stomal ulcer. Gastric acidity high. A large stomal ulcer was resected and the anastomosis converted to a Roux-Y type, an abdominal vagotomy was also done. The patient has since remained well.

Discussion

The numbers in this series are small, and in the disappointing cases there was an almost bewildering variety of antecedent procedures. Perhaps the most striking fact is that stomal ulceration following uncomplicated Polya gastrectomies (5 cases) or gastroenterostomy (4) was always completely relieved by transthoracic vagotomy.

Study of the literature suggests that, after gastrectomy, the operation of choice is vagotomy alone, which may be expected to relieve stomal ulceration in three cases out of every four (table II). Our figures support this view with 13 successes in 19 cases. Walters (1959) has suggested that stomal ulceration following gastroenterostomy is somewhat less favourably affected by vagotomy alone (table II) and that in these cases gastric resection is to be preferred. Gastric resection, however, is an operation with its own mortality and morbidity, and we have chosen to try the lesser procedure first. The fact that this succeeded in all 4 indicates that, if the gastroenterostomy is well placed and functioning satisfactorily, transthoracic vagotomy is a sound procedure.

TABLE II—PREVIOUSLY REPORTED RESULTS OF VAGOTOMY FOR STOMAL ULCER

On stomal ulcer after Roux-Y gastrectomy the literature is not informative. Some surgeons are at present performing an elective Roux-Y gastrectomy subtotally without vagotomy for duodenal ulcer, and a proportion of recurrences must surely be expected. A priori thoracic vagotomy should relieve such ulceration. Our own practice has been to employ vagotomy as a routine at the time of the gastrectomy or deliberately across the chest at the same or a second operation in cases of difficulty. Of a series of such operations (Wells and Johnston 1955) stomal ulceration has been suspected in only one. In that one case (which we have mentioned above) the diagnosis was neither confirmed nor disproved, the symptoms were not relieved, but the patient, a chronic alcoholic, has been admitted to a mental institution. Nothing can be deduced except that he was a bad subject for any operation.

Our two cases in which stomal ulceration persisted after thoracic vagotomy are of special interest. It is disturbing that despite removal of the pyloric antrum and resection of the vagus nerves—attempted and apparently achieved from both below and above the diaphragm and confirmed histologically—enough acid remained or recurred to provoke further ulceration. How this residual acid was produced remains in some doubt. We do not know whether resection of the nerves was incomplete, whether regeneration took place, or whether a hormonal factor was responsible. But the relapses did in fact occur, and in both cases the ulceration was then apparently relieved by a high gastric resection. This satisfactory end-result presumably excludes the possibility of their being examples of the Zollinger-Ellison syndrome. Possibly the initial antral resections went insufficiently high on the lesser curvature.

Conclusions

1. Transthoracic vagotomy is simple and safe.

2. It is probably the best means of treating stomal ulceration following otherwise uncomplicated gastrectomy, or following gastroenterostomy provided the stoma is well placed and functioning satisfactorily.

3. The diagnostic proof of stomal ulceration is not always easy. Estimation of night secretion, not routinely available at the time of this study, may prove invaluable. Persisting acid is a reasonable indication for vagotomy.

4. On a-priori grounds, vagotomy is necessary in operations of the Billroth I type for duodenal ulcer. If acidity persists after abdominal vagotomy, thoracic vagotomy should be undertaken as an adjuvant.

5. In patients who have undergone bizarre or multiple operations on the stomach and duodenum accurate diagnosis may be difficult. The surgeon must weigh the dangers and complications of a further abdominal operation against the advantages of actually seeing the lesion. In the presence of pain suggestive of ulcer, and of continued night secretion of acid, thoracic vagotomy is safe and worth while.

6. In some late and complicated cases, disappointments are inevitable whatever is done. It is sententious and not really helpful to suggest that the solution lies in more careful selection in the first place.

SENIOR REGISTRAR, THE MAUDSLEY HOSPITAL, S.E.5

THIS case of hypopituitary coma followed by organic psychosis seems worthy of record because the coma was reversed dramatically by treatment and the patient recovered completely from the psychosis.

Case-report

A woman, aged 46, was admitted to the London Hospital [L.H. no. 018163] from the Emergency Bed Service on June 11, 1958, with a provisional diagnosis of meningitis.

10 years previously, after the birth of her third child whom she breast-fed for 3 days only, her menstrual periods had decreased from 3–4 to 1–2 days, and their frequency from 4 to 7–10 weeks. 5 years later, after appendicectomy, menstruation ceased completely. Her general health had deteriorated, and she had lost all libido. She felt the cold more, and noticed some thinning of her hair.

2 days before admission she felt faint on getting up from a hairdresser's chair, but was able to walk home. She went to bed, and in the evening felt feverish. Next morning her family practitioner found she had a pyrexia of 102°F, but no other abnormal physical signs. Later that day her doctor's deputy found her drowsy. The following day (June 11) she was stuporose, with neck stiffness.

Course in London Hospital

She was admitted at 3 P.M. on June 11. Her temperature was 101.6°F and her blood-pressure 105/60 mm. Hg. She was well nourished, and her skin was soft, pale, and dry. The hair on her head was soft and normal in distribution, but on her eyebrows and pubes it was scanty, and in the axillæ absent. She opened her eyes in response to her name, but she would not obey simple commands, and she resisted examination, responding violently to painful stimuli. She had head retraction, but Kernig's sign was negative. The central nervous system was otherwise normal. Respiration was irregular, and she yawned frequently. Some lymph-nodes in the left side of the neck were tender.

Lumbar puncture revealed clear cerebrospinal fluid (C.S.F.) under normal pressure, containing 10 lymphocytes per c.mm. and 40 mg. protein and 35 mg. sugar per 100 ml. The blood-sugar was 38 mg. per 100 ml., and the sodium, potassium, and chloride were normal, but the serum-bicarbonate was reduced to 20 mEq per litre. Her total white-cell count was 12,700 per c.mm. (polymorphonuclears 62%), and the erythrocyte-sedimentation rate was 30 mm. in the 1st hour (Westergren).

At 8 P.M. she was given 50% glucose 40 ml. and hydrocortisone 100 mg. intravenously, without alteration in her level of consciousness. A stomach-tube was passed, and 20% glucose 150 ml. was given hourly. At midnight her blood-pressure had fallen to 90/70 and a solution of dextrose 4.5% and saline 0.25% was given intravenously. At 3 A.M. the blood-pressure was unchanged, and she responded to pain. But at 5.25 A.M. the systolic pressure had fallen to 70 mm. Hg and a solution of noradrenaline 4 mg. in normal saline 500 ml. was given in the drip. At 5.30 A.M. her blood-pressure had risen to 100/75, and at 5.45 A.M. (i.e., 20 minutes after starting the noradrenaline drip) she spoke her first rational words, saying she was comfortable, without pain, and not feeling cold. At 9 A.M. the blood-sugar was 222 mg. per 100 ml.

Noradrenaline had to be continued intravenously for 5 days to keep the blood-pressure in the normal range. She also had hydrocortisone 550 mg. in the first 22 hours, followed by cortisone 150,100, and 50 mg. daily in the 1st, 2nd, and 3rd weeks respectively. Penicillin was given for 12 days, and vitamin-B complex with ascorbic acid ('Parenterovite') 4 ml. daily for a week. Subsequent blood-sugar and serum-electrolyte estimations were normal.

An electroencephalogram (E.E.G.) on June 18 showed symmetrical rhythmic activity of 5–7 cycles per sec. at a voltage of 30–40 μV, without blocking response to visual attention, suggesting generalised disturbance and slowing of cerebral activity. At lumbar puncture on June 16 the C.S.F. contained 4 lymphocytes per c.mm. and 40 mg. protein per 100 ml. The chest and skull were normal radiographically.

After the period of coma she was uncooperative, attempting to remove the intravenous drip and the nasoœsophageal tube, and she was incontinent most of the time. She was deluded, thinking the house physician was her husband and that the nurses were the students' wives. On June 27 (16 days after admission) she became violent, shouting and throwing food at other patients, and she was transferred to the Maudsley Hospital.

Course in Maudsley Hospital

The patient's mental state fluctuated unpredictably, her behaviour ranging from apathy (when a nurse had to help her to dress) to restlessness, with shouting and aggressive outbursts. Her talking ran parallel with her behaviour, and at times she persistently importuned the staff with various requests. Her mood likewise fluctuated: at first she was usually agitated, tearful, and sometimes suspicious, but later she was more often euphoric. Her memory was seriously at fault: orientation was always imperfect and sometimes grossly incorrect. She misidentified the staff as near relatives, and again thought one of the doctors was her husband. She was unable to concentrate on simple tasks for long, and easy calculations were performed either incorrectly or not at all.

Her mental disturbance created a considerable nursing problem, but from Aug. 8 (2 months after the coma) the fluctuations settled into a calmer, rather foolish, euphoric state. She recognised people correctly, and only made moderate mistakes in orientation. On Aug. 18 she discharged herself from hospital.

Between June 30 and Aug. 18, while the patient was taking cortisone, the blood-sugar did not fall below 88 mg. per 100 ml., the protein-bound iodine ranged from 3.3 to 5.3 mg. per 100 ml. and the radioiodine-uptake neck/thigh ratio was 3 (both within normal range), the thyrotrophic hormone was 4.6 milli-units per 100 ml. (normal 10–20). The E.E.G. on July 4 still showed symmetrical generalised abnormality, with postcentral activity at 8 and at 6–7 cycles per sec., as well as at 2–4 cycles per sec., all of which now tended to block when the eyes were opened, but by Aug. 7 the alpha-rhythm was at 9 cycles per sec., with much less slow activity.

Follow-up

Since leaving hospital the patient has been seen regularly, and she has taken cortisone 25 mg. daily. At first she was still liable to mood changes and her concentration was impaired, but in September, 1958, her husband thought she was better than she had been since her last child was born. She was cheerful and alert, and her libido had returned to normal. No abnormality could be detected in her mental state, and she looked very well. By October, 1958, she was doing her housework and helping in her husband's shop, being able to calculate quickly and accurately.

Discussion

Mechanism of Hypopituitary Coma and Response to Treatment

Many metabolic factors may precipitate coma in patients with hypopituitarism (Caughey 1958), and our patient certainly had an intercurrent infection, hypoglycæmia, and hypotensive changes. But hypotension per se, as opposed to postural hypotension, is not mentioned as a cause of coma by Caughey nor by Sheehan and Summers (1952).

Sheehan and Summers wrote: "It is not easy to assess the value of treatment of hypopituitary coma, because if the patients are left without treatment some of them recover from the coma spontaneously and some die. Thus the only indications of the efficacy of any particular treatment are the rapidity of the clinical response and the proportion of the patients treated in this way who do show a response "

We consider that this patient would have died if noradrenaline had not been given, and that the rise in the level of consciousness from coma to rational spontaneous speech within 20 minutes indicates that hypotension was an important contributory factor in this case Finnerty et al (1954) showed that a fall in mean blood-pressure of 29–80 mm Hg can cause alterations in consciousness, although variation between individuals is wide

The combined action of hypoglycæmia and hypotension was displayed in a group of schizophrenic patients who—Marley (1956) found—could not be rendered comatose with 400–500 units of soluble insulin but required in addition the hypotensive effect of hexamethonium and the upright posture early in the hypoglycæmic period

Mechanism of Production of Psychosis

If coma was due to altered metabolism of the central nervous system associated with hypotension, hypoglycæmia, and hypocorticism, then the transient organic psychosis is likely to have resulted from damage, albeit reversible, from the same causes

The functional and pathological changes due to hypotension and hypoglycæmia are very similar After operations in which the blood-pressure was below 80 mm Hg, Berg et al (1957) showed that disturbances in the E.E G lasted a few days Permanent and profound mental changes were described by Allison (1956) and Bedford (1957) Similarly, delayed recovery from the effects of hypoglycæmia is well known, the distribution of neuronal necrosis in fatal cases was shown to be similar to that of anoxic lesions (Lawrence et al 1942) Experimentally Gellhorn et al. (1938) found that both the anoxic stimulus of 6 2% oxygen and that of hypoglycæmia of around 40 mg per 100 ml were required to produce Cheyne-Stokes respiration in dogs

The relation between the adrenocortical and pituitary hormones and cerebral activity is complex Depression and paranoid psychoses have been reported in patients with Addison's disease, cortisone or hydrocortisone producing the greatest restoration of mental capacities (Woodbury 1958) Mental torpor, depression, and delusions were often observed in proven cases of hypopituitarism (Sheehan and Summers 1949), and the loss of alpha-rhythm in the E E G in such cases was noted by Hughes and Summers (1956) It seems unlikely in our case that the mental changes were due to excess cortisone, as disorientation is not characteristic of such psychoses, although organic psychosis with delusions and hallucinations due to excess cortisone was recorded by Glaser (1953) But our patient's eventual return to the wellbeing which existed 10 years previously may be attributable to continued treatment with cortisone.

The relative contribution of hypotension, hypoglycæmia, and endocrine disturbances in producing coma and psychosis in this case must remain conjectural

Summary

A 46-year-old woman with hypopituitarism was precipitated into coma by an infection and failed to regain consciousness after the administration of glucose and hydrocortisone, but when the fall in her blood-pressure was reversed with noradrenaline intravenously she was able to speak rationally within 20 minutes

After the coma she had an organic psychosis which lasted for 3 months From this she recovered completely

The patient was under the care of Sir Russell Brain and Sir Aubrey Lewis, and we wish to thank them for their encouragement and help with this paper

From the Brompton Hospital, London, S W 3

FIVE years ago, Hoyle, Nicholson, and Dawson described the immediate results of treating 142 patients with antituberculous drugs for at least nine months At that time only 63 of the 142 patients had been observed for more than a year after completing treatment, and so the eventual outcome of this form of therapy could not be assessed We review here the progress of these patients over the eight years in which they have been treated and subsequently observed

Present Investigation

The detailed analyses made for the original study were lost in a fire It is probable that all the patients in that series have been included in the present one, as a systematic review of the records yielded 193 patients fulfilling the requirements for inclusion. This rather larger number is made up by those in our care (C H and H N) as well as those originally in the care of the late Dr Andrew Morland who were supervised by one of us (H N)

All patients who received antituberculous drugs for at least nine months before June, 1955, are included. 171 of these patients have been observed for two years, and 134 for three years, after completing drug treatment. 75 of them were treated surgically and by other methods as well as with drugs, but for the other 118 patients, drug therapy was the only definitive treatment. The two groups were similar as regards

TABLE I—EXTENT OF DISEASE AND TREATMENT OF 193 CASES OF PULMONARY TUBERCULOSIS

Extent of disease*	Drugs only	Surgery	Total
I	23	16	39
II	57	42	99
III	38	17	55
Total	118	75	193
Cavitation	60	56	116

* This is classified according to Foster-Carter et al (1952) class I not more than one zone in one lung involved class II unilateral or bilateral disease involving two or three zones, class III, bilateral disease affecting four or more zones

the presence of cavitation, but a rather higher proportion of patients treated with drugs alone had extensive disease (table I)

152 patients were receiving antituberculous drugs for the first time 41 had had previous treatment for short periods, regarded as inadequate by present standards, and 35 of these were in the group of 118 patients treated by drugs alone

Radiographic evidence of cavities was established and closure confirmed by tomography in almost all cases Nodules were defined as uniformly dense foci over 1 cm in diameter, in the plain film or tomograph, whichever was the greater When bacterial resistance was measured the following standards were used

	*Streptomycin**	*P A S**	*Isoniazid**
Partially resistant	3	2	1 0
Resistant	10	10	5 0

* μg per ml

Progress was measured mainly by bacterial and radiographic methods Sputum concentrates were examined monthly and cultures made until they repeatedly failed to grow *Mycobacterium tuberculosis* Radiographic progress was followed with monthly posteroanterior films The final results of treatment were judged by the ability of patients to resume and continue their normal lives Relapse was recognised by radiographic extension of disease, by the appearance of cavitation, or by return of a positive sputum

TABLE II—DURATION OF DRUG TREATMENT

—	No of patients	Duration of treatment (mos)			
		9–12	13–18	19–24	Over 24
Extent of disease					
I	39	24	6	6	3
II	99	33	24	30	12
III	55	7	19	10	19
Total	193	64	49	46	34
Surgery and artificial pneumothorax	75	33	21	12	9

Methods of Treatment

Drug regimens varied from patient to patient and over the years of the study, but all patients were treated with combinations of two or three drugs accepted as effective The doses used were streptomycin sulphate 1 g daily, combined dihydrostreptomycin 0 5 g and streptomycin 0 5 g daily, *p*-aminosalicylic acid (P A S) 6 g twice daily, and isoniazid 100 mg twice daily The duration of drug treatment increased over the years mainly because of the evolution of ideas upon prolonged therapy, but it was also influenced by the extent of the disease Patients treated surgically received less drug treatment (table II)

With 1 exception all patients were admitted to hospital and rested in bed for the first three to six months, most of them spent about six months at a sanatorium afterwards Those with cavities were usually nursed with the cavity dependent for the first few months In addition to antibacterial treatment 60 patients were treated surgically and 15 by artificial pneumothorax The indications for additional treatment varied, sometimes withholding this was considered unjustifiable when the results of drug therapy alone were still unknown, especially in dealing with thick-walled cavities which persisted after six months' drug treatment and bed rest there is now little doubt that some of these cavities would have closed after longer treatment with chemotherapy alone (table III)

TABLE III—INTERVALS FROM START OF TREATMENT TO CAVITY CLOSURE

Time of closure (mos)	Drug treatment alone	Drugs plus surgery and other measures
0– 6	30	34
7–12	15	15
13–36	4	4
Total	49*	53
Failure to close	11	3

* In 4 other patients cavity closure was achieved with drugs, but operation was performed subsequently

Results

Sputum Conversion

Myco tuberculosis was isolated from the sputum of 140 of the 193 patients Only 1 patient has a persistently positive sputum after completing treatment, although in 5 others bacilli continued to appear in the sputum for a year, in these the sputum became negative within the next two years while the same drug regimen was continued. Of 118 patients treated with drugs alone, 79 had initially a positive sputum which became negative in all but 1

Cavity Closure

116 of the 193 patients had cavities, which were closed by drugs alone in 53 instances, in the earlier years of the study many patients were treated surgically within a year after drug treatment was started, and for this reason the influence of drug therapy on cavity closure cannot be fully assessed The intervals from the start of treatment to cavity closure are shown in table III

In 30 out of 60 patients treated by drugs alone the cavities closed within six months, and in a further 19 after six months to three years 11 patients in this group were left with persisting cavities, but in only 1 did the sputum remain positive, in 8 the sputum was negative within a year, and in the 2 others within three years

14 patients of the whole series had persisting cavities at the time drugs were stopped 9 of these are alive with

TABLE IV—DATA ON 23 PATIENTS WHO RELAPSED

Case no	Extent of disease	Previous drug treatment	Length of drug treatment	Interval since stopping treatment	Type of relapse *	Sputum	Sensitivity †	Outcome

* The site was new in case 1, and the original site in the remainder

† Satis indicates full sensitivity to streptomycin (S), P.A.S , and isoniazid

open cavities and a negative sputum, but 6 had a positive sputum at the end of treatment or subsequently, 3 have died of tuberculosis and 1 of respiratory failure

Nodules

Of the 193 patients 35 had nodules, which were resected in 12 The other 23 all progressed satisfactorily under treatment with drugs alone In 5 the lesions disappeared rapidly, and in 12 they shrank gradually and formed a linear shadow, in 5 the nodules remained the same size, and in 1 the progress could not be assessed adequately 16 of the 23 patients have been followed for over three years after completing antituberculous drug therapy, and in no instance did cavitation occur within the solid lesion of the 12 patients treated by lung resection only 2 received this sort of therapy because of cavitation within the nodule.

Relapse

Of the 193 patients, 23 (12%) relapsed from the beginning of treatment up to four years after drugs were stopped (6 of these patients relapsed while receiving chemotherapy, but 17 [8%] relapsed after drug treatment was completed) Of 118 patients treated with drugs alone, 3 relapsed during treatment and 15 (13%) relapsed subsequently Details of these patients are given in table IV

Of the 23 patients who relapsed, 13 had advanced disease and 8 had disease of moderate severity (table IV) 15 of the 23 had received nine to fifteen months' drug treatment and relapse occurred up to four years after treatment was stopped 8 patients relapsed who had had over eighteen months' continuous drug treatment The interval between discontinuance of drug treatment and relapse ranged from three months to four years, in 6 patients the interval was over two years

19 of the 23 patients who relapsed are now well, with their disease stabilised 5 of them were treated surgically and 2 had an artificial pneumothorax 6 received further chemotherapy for about two years, while the remaining 6 were not given any further treatment but have remained well 1 other patient is at present receiving further chemotherapy The remaining 3 patients of the 23 who relapsed have died—2 from non-tuberculous causes and 1 from advanced tuberculosis of many years' standing

Deaths

11 patients died during the eight years of observation—5 from tuberculosis, 3 from respiratory failure, and 3 from unrelated causes

Drug Toxicity

60 of the 193 patients complained of symptoms attributed to antituberculous drug (table V) Vestibular symptoms usually disappeared when streptomycin was discontinued Other side-effects were controlled with appropriate treatment, and therapy was usually not curtailed.

Outcome in 134 Patients Followed for Three Years after Completion of Drug Treatment

123 of the 134 patients have survived 6 have open cavities but are well with a negative sputum, 17 have relapsed at some time within the three years, and 6 have severe breathlessness with bronchitis and are respiratory cripples 116 are well and have resumed work

Return to Work

Of 174 cases where records are available, 106 patients had returned to work in a year or less, 61 in two years, and 7 after more than two years

TABLE V—SIDE-EFFECTS OF DRUG TREATMENT

Drug	Side-effect	No of cases
Streptomycin	Tinnitus	2
	Giddiness	14
	Deafness	2
	Drug rash and fever	17
P.A.S.	Drug rash and fever	10
	Goitre	1
	Severe nausea	12
Isoniazid	Burning feet	1
Uncertain	Angioneurotic œdema	1

Discussion

The aims of antituberculous drug therapy are to achieve maximum resolution and permanent healing of the disease Clinically these may be measured by negative sputum-cultures, closure of cavities, the patient's capacity to lead a normal life and the absence of relapses

In the present group of patients the outcome with regard to sputum conversion has been very satisfactory Of the 79 cases treated by drugs alone in which the sputum was initially positive, all but 1 became negative, although in some cases the sputum ceased to be positive only after many months of drug treatment, and in 5 instances sputum conversion was achieved after more than a year of continuous chemotherapy

For reasons already discussed, we are unable to assess the effectiveness of antituberculous drugs in closing cavities, but we should like to emphasise that cavity closure after six months' therapy occurred in about a third of those cases treated with drugs alone Failure to achieve cavity closure at six months should not be regarded as failure of chemotherapy Cavitation persisting with a negative sputum has not in our series proved to be a precursor of relapse, but numbers were small. However, Raleigh (1957) suggests that this may be so, 50% of his 123 patients with negative sputum and persisting cavities relapsed over a period of two and a half years, following an average of sixteen months' treatment If cavities persist and surgery is excluded, it is probably wise to continue antituberculous drug treatment beyond two years Persisting cavitation in association with a positive sputum proved as serious as expected, in that 4 out of 6 such patients died.

In this series there are 182 surviving patients, and 174 are leading normal lives 6 have chronic bronchitis and various degrees of respiratory failure impairing their capacity for work. Of 134 patients followed for over three years after stopping chemotherapy, 122 have survived and been rendered non-infectious, but complacency is dispelled when the numbers of patients who have relapsed are considered Unfavourable radiological change or positive sputum occurred in 23 of the 193 patients—about 12% Of these 23 patients, 7 had had previous chemotherapy and 7 were longstanding cases of pulmonary tuberculosis and had received various other treatments in the past Among these patients who relapsed, radiological extension of the disease with cavitation was seen most frequently, in fewer patients extension occurred without cavitation. Spread of the disease to a new site or the finding of a positive sputum in the absence of radiological change was rare. 8 patients relapsed after receiving chemotherapy for more than eighteen months 1 patient was known to have taken the drugs irregularly Another had pneumoconiosis complicated by tuberculosis, while a further patient was found to have a mucocœle of the bronchus but no definite evidence of tuberculosis In the 4th patient cavity closure was believed to have occurred within three months of starting treatment, subsequently three months after treatment was stopped tomography demonstrated a cavity in the original situation, casting some doubt on the completeness of the first tomographs The 5th patient had a persisting cavity under a thoracoplasty with a positive sputum On routine tomography the 6th was found to have unsuspected rarefaction in a nodule approximately a centimeter in diameter, no further treatment was given, and a year later tomography disclosed a small stellate shadow at the site of rarefaction. 2 patients had had previous inadequate chemotherapy before their definitive course, and afterwards developed slight extension of their disease 1 patient is at present under treatment, but the other 7 have done well and are living normal lives with their disease apparently stabilised In general the outcome in patients who relapsed is satisfactory in that 19 of 23 are well with their disease inactive

Microbial persistence must be the ultimate reason for failure of chemotherapy (McDermott 1958) At a clinical level, several factors are important Patients may fail to take the drugs prescribed, and this is now a well-recognised difficulty in long-term ambulant therapy Gastro-intestinal symptoms, so frequently produced by P A S , are particularly important in this respect The importance of drug-resistant organisms has been stressed by Ross et al (1958), but in our group drug resistance was infrequent Usually it was found in those patients who had had previous inadequate chemotherapy Previous treatment, however, may prejudice future chemotherapy in other ways as yet undetermined, encouraging microbial persistence without causing insusceptibility to drugs as shown by in-vitro methods (McDermott 1958) The length of time during which drugs should be given remains obscure Ross et al (1958) report a trend towards an inverse relationship between relapse and duration of treatment, but 63 of their patients treated for more than eighteen months had not relapsed at the time of their report, though the period of follow-up of these patients was only eighteen to thirty months Smart and Gough (1958) reported no instances of relapse in a group of 75 patients who received chemotherapy for over a year, but the majority of their patients (45/75) were followed for less than two years after completing treatment Relapse has, however, been observed in patients who have received two years' continuous drug therapy, both in the present and in other series (Raleigh 1957) This fact, together with the finding of drug-susceptible organisms in some of these cases, suggests that two years' treatment is sometimes insufficient In our view all cases of active pulmonary tuberculosis, even when very slight, should receive at least two years' drug therapy

Summary

The progress of 193 patients with pulmonary tuberculosis who received at least nine months' antibacterial drug treatment before June, 1955, has been reviewed

The duration of treatment was over eighteen months in 80 patients, and 118 were treated with drugs alone 134 were followed for more than three years after completing treatment

At completion of treatment sputum culture for *Myco tuberculosis* was negative in all patients except 1

Of 60 patients with cavities who were treated by drugs alone, the cavities closed in less than six months in 30 In a further 19 the cavities closed after persisting for from six months to three years

In each of 23 patients with nodules treated by drugs alone, the progress was satisfactory 16 of these patients were followed for over three years after completing treatment

12% of the whole group relapsed between the beginning of treatment and up to four years after drug treatment was discontinued Of 118 patients treated with drugs alone, 13% relapsed after treatment was stopped

TRANSPOSITION OF THE VISCERA AND STERILITY IN MEN

E Arge*
M B Copenhagen

Transposition of the viscera may be partial or complete In 1947 Torgersen collected 129 cases, 123 of which were complete

The reported frequency differs In necropsy material it has been found to be 1 in 6000 and in a mass chest survey 1 in 6500 (Blegen 1949) Torgersen (1947) found that the frequency was 1 in 8000–10,000 Familial occurrence has been reported several times (Call and Woolf 1934, Cockayne 1937, Feldmann 1935, Feldmann and Needle 1934, Torgersen 1947 a and b) Torgersen reported consanguinity in 7 3% of the cases Published accounts seem to indicate that cases may occur in the line of ascent and descent (Doolittle 1907, Torgersen 1947 a and b)

The ætiology is unknown It has been suggested that the anomaly may be related to twins one of which has been absorbed in utero

As regards external signs Ebstein (1923) reported that the right half of the scrotum hung further down than the left in 28 out of 36 men with complete transposition of the viscera Left-handedness is not believed to be commoner in persons with visceral transposition than in others (Cockayne 1937)

The diagnosis may be made by percussion or auscultation, but should be confirmed by electrocardiography and by X-ray examination of the chest and gastrointestinal tract (Wood and Blalock 1940)

So-called Kartagener's syndrome is said to be common in these cases It consists in visceral transposition, bronchiectasis, and malformation of the nasal sinuses (Cockayne 1937, Karani 1952) Torgersen (1947) found bronchiectasis in 8% of his cases

No mention seems to have been made of sterility or reduced fertility in cases of visceral transposition

Present Series

My series consists of 4 cases (3 male and 1 female) of complete visceral transposition among two sibships Consanguinity in a high degree is present, the fathers are brothers and the mothers sisters, so the children are double first cousins In addition, the parents have common greatgrandparents (fig 1)

Of external signs which might indicate visceral transposition, in all 3 men the right half of the scrotum hangs lower than the left and 2 of them are left-handed There are no other external peculiarities, and all the men are of masculine build

All have a history of mild attacks of asthma, their colds have tended to be lengthy with much expectoration 1 of the men has undergone an operation for frontal sinusitis, and another has diabetes mellitus The woman has had an operation for acute appendicitis, and the appendix was found to be localised to the left side of the abdomen

Electrocardiographic tracings showed in all cases total inversion of lead I and transposition of leads II and III (fig 2)

Radiography in case D (see fig 1) showed the liver in the left side of the abdomen, and total inversion of the stomach and colon was found after administration of contrast medium, chest radiography revealed complete transposition of the heart (figs 3–5)

---

* 20, Mantziusvej, Hellerup, Denmark

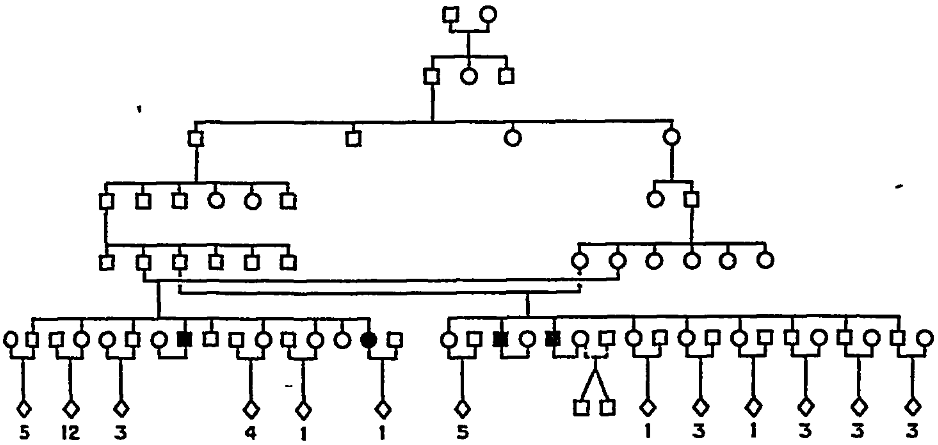

Fig 1—Family tree showing two sibships of 9 members each. In one there is 1 man and 1 woman and in the other 2 men with complete transposition of the viscera.

Other members of the family, who were scattered all over the country, have been examined, nearly all were examined by electrocardiography and chest radiography and the remainder only by percussion and auscultation and, in males, inspection of the scrotum. No sign of visceral transposition was detected.

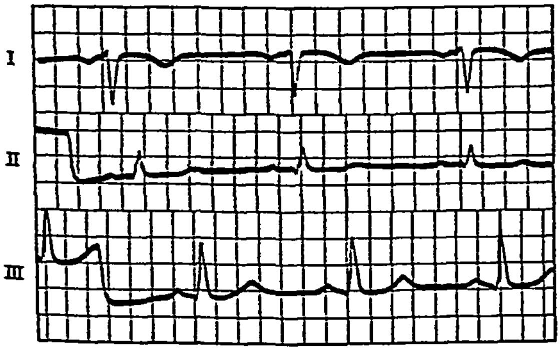

Fig 2—Case D electrocardiogram showing total inversion of lead I and transposition of leads II and III.

The family tree (fig 1) shows 9 siblings in each sibship. All who are married have children except the men with visceral transposition, whereas the woman with visceral transposition has 1 child. Moreover, 1 of the men—case D—is married to a woman who has 2 sons born prior to the present marriage.

I tried to investigate the affected men as regards fertility. But 2 of them were over 50 years of age and so were their wives, and they refused to be examined. The 3rd man (case D), however, is married to a woman of child-bearing age, who had given birth to 2 sons before the present marriage, and they want children, so he declared himself willing to be examined.

Dr Richard Hannen investigated case D's semen. The specimen consisted of 3 5 ml. of rather viscid, slightly transparent seminal fluid. Three-quarters of an hour after ejaculation 91% of spermatozoa were immobile, the survival-time was less than twenty-four hours after the ejaculation. Spermatozoa numbered 95,000,000 per ml. and the total number 333,000,000, 47% had abnormal head shapes. Dr Hammen concluded that fertility was much reduced.

The genitalia appeared normal except for the right half of the scrotum hanging lower than the left, the testes were walnut-sized and firm.

A biopsy specimen of the right testis (examined by Dr H Olesen) contained particles of testicular tissue with numerous tubules, most of these were of normal width, but a few were somewhat narrow with mild fibrous thickening of the tubular walls. Throughout, they were lined with very tall columnar epithelium, containing all elements and with very brisk spermiogenesis, but some spermatozoa were thin with somewhat pear-shaped heads. There were no clear degenerative changes of the epithelial tissue. The interstitial tissue was sparse, with very small groups of Leydig cells, no inflammatory reaction. Dr H Olesen concluded that the testicular tissue showed slight degenerative changes and brisk, somewhat abnormal spermiogenesis.

Basal metabolic rate +11% (determined twice). Hormone analyses: Gonadotrophins below 50 milli-units, total and fractionated 17-ketosteroids normal.

The cases in this family suggest that men with transposition of the viscera may be infertile or subfertile. This point should be further investigated in other patients with the condition, and, if confirmed, a watch should be kept for transposition of the viscera among patients at male sterility clinics.

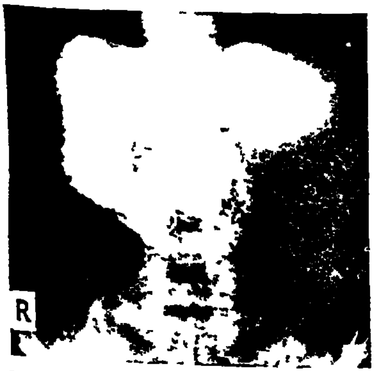

Fig 3—Case D X-ray film after barium meal showing stomach on the right side.

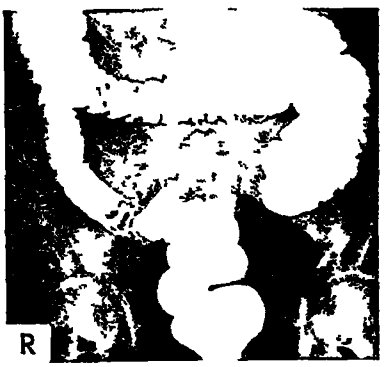

Fig 4—Case D X-ray film of colon after barium enema showing ascending colon on left and descending colon on right.

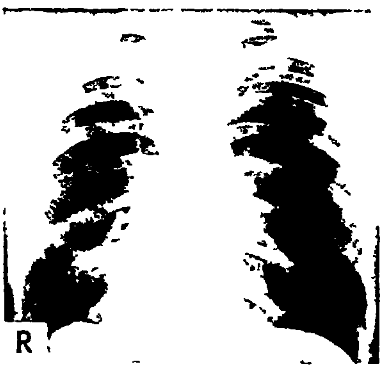

Fig 5—Case D chest radiograph showing transposition of heart.

Summary

Two sibships, each of 9 members, includes 4 cases of transposition of the viscera (3 men and 1 woman)

There is a high degree of consanguinity, as their mothers are sisters and their fathers brothers, and the parents have common greatgrandparents All except 1 woman and 1 man are married, and all those who are married have had children except the men with visceral transposition 1 of these, married to a woman who had borne 2 sons before the present marriage, was investigated more closely, examination of seminal fluid and biopsy of the testis suggested reduced fertility

PRODUCTION OF VIRÆMIA IN CORTISONE-TREATED MONKEYS WITH THE ATTENUATED BRUNENDERS STRAIN OF TYPE-1 POLIOVIRUS

C R Coid
B Sc Edin , Ph D Reading, M R C V S

T S L Beswick
M A , M D Cantab , M R C P

From the Biological Standards Control Laboratory, Medical Research Council Laboratories, London, N W 3

Much of the information on the infectivity for monkeys of the strains of poliovirus used for the production of formalin-inactivated vaccines has been obtained from investigations with virulent strains (Bodian 1956, Eklund et al 1956, Gebhardt and Bachtold 1956, Syverton et al 1956) In Britain, however, the attenuated Brunenders strain of poliomyelitis virus is used as the type-1 component of poliomyelitis vaccine (Biological Standards Control Laboratory 1957) and information on the infectivity of this strain for monkeys was required so that satisfactory procedures could be adopted for testing vaccines manufactured in this country A series of experiments was carried out, therefore, in which cortisone-treated cynomolgus monkeys were injected with varying doses of the Brunenders strain These experiments provided information on the occurrence of viræmia and on the ability of the strain to produce lesions in the central nervous system

Materials and Methods

Animals

Cynomolgus monkeys (*Macaca irus philippinensis*) weighing between 1 4 and 1 8 kg were used They were in good condition and had been in quarantine for at least a month before use Before injection of virus each animal was anæsthetised by an intraperitoneal injection of pentobarbitone sodium and also given 300,000 units of long-acting penicillin and 0 4 g of chloramphenicol intramuscularly All monkeys were given 150 mg cortisone intramuscularly 2 days before injection of virus, and 100, 50, 75, 50, 50, 75, 50, and 50 mg respectively at 0, 2, 4, 7, 9, 11, 14, and 16 days thereafter

Inoculation of Virus

Suspensions of living virus were prepared in either commercial poliomyelitis vaccine or medium 199 (Morgan, Morton, and Parker 1950) as described previously (Coid, Beswick, and Tobin 1960) The total dose of virus given to each monkey varied between 3 and 140 $TCID_{50}$ and was contained in a volume of 3 4 ml , each animal receiving 0 3 ml into each thalamus, 0 1 ml into each of three lumbar segments, and 2 5 ml into the right deltoid muscle

TABLE I—TIME AFTER INJECTION WHEN VIRUS WAS FIRST ISOLATED FROM THE SERA OF MONKEYS INJECTED WITH TYPE-1 POLIOMYELITIS VIRUS

Virus suspended in	No of serum samples in which virus was first isolated (days after injection)				Total
	3	7	10–11	15–18	
Poliomyelitis vaccine	4	2	2	4	12
Medium 199	1	7	3	2	13
Total	5	9	5	6	25

Isolation of Virus from Blood-serum

Blood samples were taken from the femoral vein at intervals between the 3rd and 18th day after injection and from the heart at the time of death Virus was isolated from the serum using monkey-kidney cell cultures by the method previously described, and all isolates were typed to confirm that they were type-1 poliovirus (Coid, Beswick, and Tobin 1960)

Histological Examination

At the end of the observation period, which varied from 21 to 25 days, or at the time when paralysis developed, the animals were anæsthetised with pentobarbitone sodium and perfused with formol-saline, and the brains and spinal cords were removed for histological examination (Biological Standards Control Laboratory 1957)

Results

A total of sixty-eight monkeys were injected over a period of approximately 18 months, forty-one receiving virus suspended in poliomyelitis vaccine and twenty-seven virus suspended in medium 199 Viræmia was detected in twenty-five monkeys—in twelve of those receiving virus in vaccine and thirteen of those receiving virus in medium 199 In sixteen of the twenty-five monkeys virus was isolated on one occasion only and in the remaining nine at least twice from consecutive blood samples The results, giving the time at which virus was first isolated from the blood, are shown in table I It is evident that the first isolations did not occur at any particular time after injection and that there is no obvious difference in the results obtained with virus in vaccine and virus in medium 199 It is interesting to note that 6 of the first isolations occurred as late as between 15 and 18 days after the injection of virus, and of these 2 were isolated actually on the 18th day The levels of virus found in monkeys injected with the highest dose of virus varied from minimal amounts to 10^4 $TCID_{50}$ per ml

In table II these results are compared with those obtained by histological examination When the results of both tests are taken together it is seen that thirty-three monkeys gave evidence of infection, in eight there was histological evidence only, in twelve serological evidence only and in thirteen both histological and serological

TABLE II—COMPARISON OF VIRÆMIA WITH HISTOLOGICAL EVIDENCE OF INFECTION IN MONKEYS INJECTED WITH TYPE-1 POLIOMYELITIS VIRUS

Virus suspended in	*No of animals with*			Total no of animals infected
	C N S lesions only	Viræmia only	Viræmia and C N S lesions	
Poliomyelitis vaccine	5	7	5	17
Medium 199	3	5	8	16
Total	8	12	13	33

evidence. Therefore, if histological examination alone had been made infection would have been detected in only twenty-one monkeys, and if serological examination alone had been made only twenty-five would have shown infection Again, there was no obvious difference in the results obtained with virus in vaccine and virus in medium 199

Conclusions

In the safety testing of inactivated poliomyelitis vaccine in monkeys it is important that the procedures adopted should ensure that no chance of detecting the presence of live virus is missed The experiments described, using the attenuated Brunenders type-1 strain, have shown that combining the histological examination of the central nervous system with the examination of the blood for the presence of virus is more satisfactory in detecting infection than either method alone.

It is evident also that if infections are not to be missed the examination of blood samples must be made at regular intervals during the observation period and at least up to the 18th day

From the Western Infirmary, Glasgow,
and the Vale of Leven Hospital, Alexandria

THE operation of total gastrectomy is relatively rare and is often followed by digestive and other complications

The sequelæ of the operation have been much investigated, but we have been unable to find any record of vitamin-A deficiency, with dermatological lesions or impaired night vision, developing after this operation In the course of a long-term study of the metabolic effects of total gastrectomy the five patients described in this paper were all found to be deficient in vitamin A

Material and Methods

Total gastrectomy, with œsophagojejunal anastomosis, was performed for histologically proven carcinoma in cases 1, 3, and 5 and for gastric stenosis due to corrosive gastritis in case 4, a tiny fringe of fundus was left to facilitate the anastomosis after the removal of a clinically malignant, but histologically benign, gastric ulcer in case 2, who also underwent partial pancreatectomy and who later developed diabetes mellitus At the time of this study there was no evidence of recurrent carcinoma in cases 1, 3, and 5

TABLE II—RESULTS OF VITAMIN-A-ABSORPTION TESTS

Case no	Relation to treatment	Serum-vitamin-A levels (µg per 100 ml)			
		0 hr	2 hr	4 hr	6 hr
1	Before	9	—	40	—
	After	30	20	155	65
2	Before	13	—	95	—
	After	33	258	370	358
4	Before	8	—	40	—
	After	40	35	165	90
5	Before	12	—	50	—
	After	46	248	190	89

Serum-vitamin-A concentrations were estimated by the method of Kaser and Stekol (1943)

Vitamin-A-absorption tests were carried out in four cases after an 8-hour fast A fasting blood sample and further samples at 2, 4, and 6 hours after approximately 200,000 I U vitamin-A palmitate in olive oil (7 ml. 'Avoleum', B D H) orally were collected, no food being permitted during the test. The absorption tests were repeated after treatment with oral vitamin A 100,000 I U daily for 2–3 weeks

Dark-adapted visual acuity was assessed before and 2–3 weeks after treatment with oral vitamin A, by the method of Riddell (1940, 1943), the examiner being unaware of any treatment given, or of the biochemical findings

Jejunal biopsies were obtained, without overt bleeding, using a biopsy tube (Wood et al 1949) passed under radiological control Specimens were fixed immediately in 10% formol-saline followed by formol-corrosive, and paraffin sections were stained by hæmalum and eosin, trichrome stains, mucicarmine (Southgate), van Gieson, diazo (Pearce), reticulin (Gordon and Sweet), and periodic-acid Schiff reagent.

Fat absorption was assessed over a 4-day (case 3) or 10-day balance period, the daily intake of fat being 50 g

A detailed dietary history was obtained by standard methods, particular reference being paid to the carotene and preformed vitamin-A content of the diet.

Results

Vitamin A—The results of the biochemical studies are given in tables I and II The initial value (table I) refers to the vitamin-A concentration of serum obtained from the patients when they first came under observation and stored at −20°C until analysed In four cases vitamin-A absorption tests (table II) were carried out and the estimations were made immediately The fasting values were subnormal in all cases, and, although there was evidence of absorption shown by a rise in the serum-vitamin-A concentration, the peak values were less than those obtained in normal subjects When the tests were repeated after oral treatment with vitamin A the fasting concentrations and peak values were then normal

Dark-adapted vision—Before treatment dark-adapted vision was subnormal in four cases (table I), three of whom were retested after vitamin-A therapy and all had returned to normal In the fifth case dark-adapted vision

TABLE I—DATA ON 5 CASES OF VITAMIN-A DEFICIENCY FOLLOWING GASTRECTOMY

Case no	Age (yr.)	Sex	Time since operation (yr)	Fat absorption (%)	Daily vitamin-A intake (I U)	Initial serum-vitamin-A level (µg per 100 ml.)	Skin lesions	Dark-adapted visual acuity	
								Before treatment	After treatment
1	48	F	$5\frac{3}{4}$	54	4368	4		Subnormal	Normal
2	42	M	5	79	5360	9		,,	,,
3	47	M	2	90	3178	4		,,	Not tested
4	60	M	13	88	5590	3	—	Normal	Normal
5	47	M	$1\frac{1}{2}$	76	6413	10	-	Subnormal	,,

was normal this patient had follicular hyperkeratosis of the type described in vitamin-A deficiency

Fat absorption —The amount of dietary fat absorbed was much impaired in three cases, and in the other two was just below the usually accepted lower limit of normality (table I)

Jejunal biopsies —In all instances the appearances of the jejunal mucosa obtained was considered to be within normal limits although minor variations were occasionally noted, such as slight widening of the villi (case 1) and slight reduction in total mucosal thickness (case 4)

Diet —In all cases the intake of vitamin A was within normal limits The bulk of the total vitamin A ingested was in the form of the preformed vitamin The intake of vitamin A in table I refers to preformed vitamin A only

Discussion

There is good evidence that all of these patients were suffering from vitamin-A deficiency All had very low serum-vitamin-A concentrations, and these were raised to normal in the four cases given oral vitamin A, the defective dark adaptation demonstrated in four patients was corrected by oral vitamin A in the three patients who were retested, the one patient who had normal dark adaptation had follicular hyperkeratosis which was cured by oral vitamin A None of the night-blind patients were aware of the defect, but this was not unexpected as all were city-dwellers Follicular hyperkeratosis due to vitamin-A deficiency is extremely rare in this country (Bicknell and Prescott 1953)

The ideal intake of vitamin A is not known with certainty, but a daily intake of 2500 I U is considered satisfactory (Medical Research Council 1949), and we accept that all these patients had an adequate intake well within normal limits No patient took liquid paraffin, which hinders the absorption of vitamin A, and no patient had any intercurrent disease in which vitamin-A deficiency is known to occur as a complication, diabetes mellitus no longer being considered to be a cause of perverted vitamin-A metabolism (Bicknell and Prescott 1953, Moore 1957) Under these circumstances, and because the operation was performed for different lesions, it is difficult to escape the conclusion that the deficiency is, in some way, the result of the operation One patient, not included in this series, had a normal serum-vitamin-A concentration prior to total gastrectomy and one year after operation, this suggests that the deficiency is a late result of operation possibly due to depletion of body reserves and not an immediate metabolic consequence such as might happen in pneumonia

The cause of the deficiency is an interesting problem From what is known of the biochemistry of fat and vitamin-A absorption it is reasonable to suppose that the absorption of vitamin A would be reduced in direct proportion to the degree of fat malabsorption When fat absorption is normal or only slightly impaired, and when the dietary intake of vitamin A is high, as in cases 2 and 4 in particular, it is unreasonable to ascribe the vitamin-A deficiency solely to steatorrhœa Of the cases reported here, there is only one (case 1) in which steatorrhœa alone might possibly have caused the vitamin deficiency

The view that steatorrhœa per se is a cause of vitamin-A deficiency is based largely on study of patients with gluten-induced enteropathy, many of whom fail to absorb vitamin A as judged by the test used here, but in such patients there is an anatomical abnormality of the small bowel which may be the cause of the malabsorption of both fat and vitamin A In our cases there was no evidence of any lesion comparable to that seen in gluten-induced enteropathy and sometimes seen in other types of steatorrhœa (Paulley 1954, Doniach and Shiner 1957, Sakula and Shiner 1957, Shiner 1957, 1959, Butterworth and Perez Santiago 1958) In two cases only (cases 1 and 4) there were minor histological variations which we do not regard as differing significantly from normal, similar changes were seen in control biopsy material and were obviously the result of processing This is in keeping with the general experience of those who have studied the jejunum microscopically after subtotal gastrectomy Baird and Dodge (1957) found that the jejunal mucosa was normal in twenty-three out of thirty-one patients after partial gastrectomy, the remaining eight cases showing minor variations only After partial gastrectomy Doniach and Shiner (1957) found abnormalities in the jejunal mucosa of one of their four cases, while in a series of fifteen patients with post-gastrectomy steatorrhœa described by Shiner (1959) jejunal villous atrophy, partial or subtotal, was observed in only two cases Paulley (1959) attaches more significance to minor variations than do others It is to be noted that three of our samples (cases 1, 2, and 4) were obtained after the patients had been treated for post-gastrectomy megaloblastic anæmia, and since it is known that atrophic villi may regenerate after therapy in cases of steatorrhœa, other than the gluten-induced variety, it is perhaps possible that significant changes might have been found had the samples been taken before therapy, the clinical condition of the patients did not permit this

The limitations of the absorption test as a means of estimating the degree of absorption of ingested vitamin A in the same individual, as well as between individuals, are well known (Hillman and Becker 1957, Volwiler 1957), but it does appear that our patients can absorb at least some of the large dose of vitamin A used in the test The low peak values obtained in the initial tests, while the patients were in a grossly deficient state, may represent rapid clearance of the absorbed vitamin to body tissues—a feature not evident when the tests were repeated after a period of treatment when the body stores would have been replenished

The cause of the deficiency in these patients with normal dietary intakes, normal histological appearances of the small bowel, and apparently normal absorption of massive doses of vitamin A is obscure, but may well lie in a multiplicity of factors resulting from the operation which act to the detriment of the absorption of physiological amounts of vitamin A but do not apparently hinder absorption of massive amounts, as far as can be judged by the test used

Relatively little is known with certainty about the site of absorption and the factors governing the absorption of vitamin A in man even when the gastrointestinal tract is intact There is good evidence that the site of maximal absorption in rats and ruminants is in the upper small bowel (Popper and Volk 1944, Eden and Sellers 1949) and there is some evidence that this may be so in man (Fingerland 1957) What is known of the factors governing absorption is based largely on the results of absorption tests of the type used here and is therefore liable to misinterpretation

An adequate intake of fat in the diet and the presence of lipolytic enzymes in bile appear to be necessary for the normal absorption of vitamin A, while decreased intestinal motility apparently impairs absorption (Bicknell and Prescott 1953, Moore 1957) All our patients had a normal fat intake The most obvious abnormality in our patients is the loss of the reservoir and digestive function of the stomach with consequent premature passage of a large mass of inadequately digested food relatively low down in the small bowel and rapid transit through the small bowel past the absorbing sites We have been impressed by the very rapid transit of a barium bolus in our patients

Other factors which may also be important are the limited time available for mixing of the bolus with, and digestion by, pancreatic enzymes before the mass reaches the absorbing site, the limited amount of pancreatic enzymes and bile which will be available particularly where the anastomosis is œsophagojejunal rather than œsophagoduodenal (notably where partial pancreatectomy has also been performed as in case 2), and finally the unknown quantity of abnormal bacterial proliferation in the small bowel Until an absorption test using physiological quantities of vitamin A is devised, it is unlikely that the precise cause of the deficiency will be found

The deficiency of vitamin A in our patients does not seem to be a very severe matter in itself, and it does not seem to be comparable to the gross degrees which cause keratomalacia Nevertheless we cannot regard the deficiency as other than detrimental to good health, and it would seem desirable to give vitamin A to patients after total gastrectomy as a prophylactic measure On the basis of the present investigations, which are continuing, a course of oral vitamin A, 100,000 i u daily for 2 weeks every six months, seems advisable. On this regime there is no risk of the toxic effects which might result from large daily doses for long periods

Summary

Five cases of vitamin-A deficiency in patients who had undergone total gastrectomy are reported Four of the patients were night-blind and the fifth had follicular hyperkeratosis These abnormalities were corrected in the four cases given oral vitamin A

The deficiency is of complex origin, and steatorrhœa is not the only causal factor

Vitamin A should be administered prophylactically to patients who have undergone gastrectomy

We are grateful to Dr J A W McCluskie, Prof D F Cappell, Prof W J B Riddell, and Dr E B Hendry for advice and criticism, and to Dr A C Macdonald and Dr D Horne for facilities at the Vale of Leven Hospital, to Mr Arthur Ness, of the department of biochemistry, Western Infirmary, Glasgow, for the serum-vitamin-A estimations, and to Miss M G McCombie, of the dietetic department, for the dietary histories, and to the physicians and surgeons of the Western Infirmary who have allowed us to study their patients

Preliminary Communication

THE REJECTION OF RENAL HOMOGRAFTS INHIBITION IN DOGS BY 6-MERCAPTOPURINE

FOLLOWING the report by Schwartz and Dameshek[1] that 6-mercaptopurine can make rabbits tolerant to human serum albumin antigen, I have used this drug in an attempt to modify the rejection of renal homografts in dogs

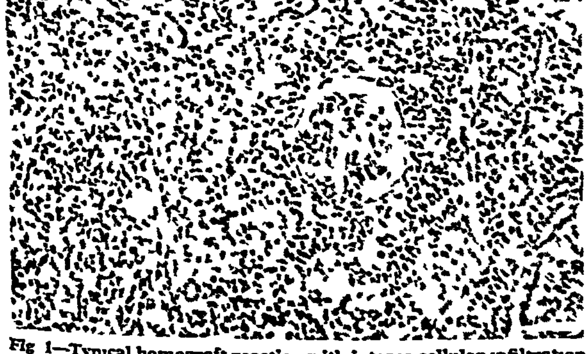

Fig 1—Typical homograft reaction with intense cellular infiltration in a kidney 10 days after transplantation (Hæmotoxylin and eosin. ×120)

INVESTIGATION

The donor and recipient dogs were of different breeds Under intravenous pentobarbitone anæsthesia, a kidney was removed from the donor and transplanted to the right iliac fossa of the recipient, the renal vessels of the donor's kidney were anastomosed to the iliac vessels of the recipient and the ureter was implanted into the bladder

Given by intramuscular injection, in a dosage of 6 mg per kg body-weight daily from the operation, 6-mercaptopurine proved highly toxic On the other hand, though the animals died from its effects in 10–14 days, they showed no signs of the homograft reaction described by Dempster[2] and Simonsen et al[3] (fig 1) On a lower but still toxic dosage in a dog

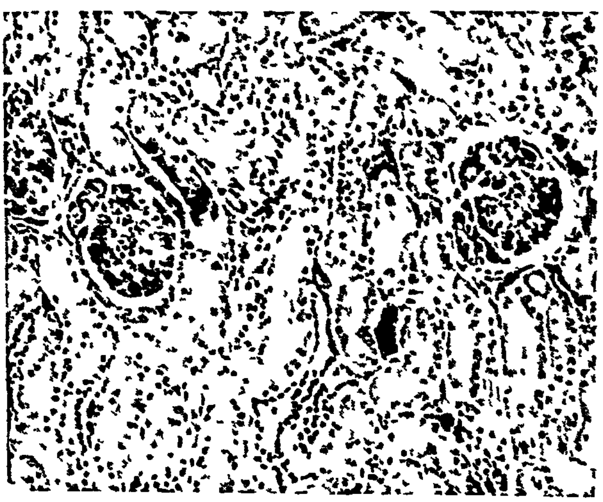

Fig 2—Renal homotransplant after 47 days on 6-mercaptopurine No evidence of homograft reaction (H & E ×120)

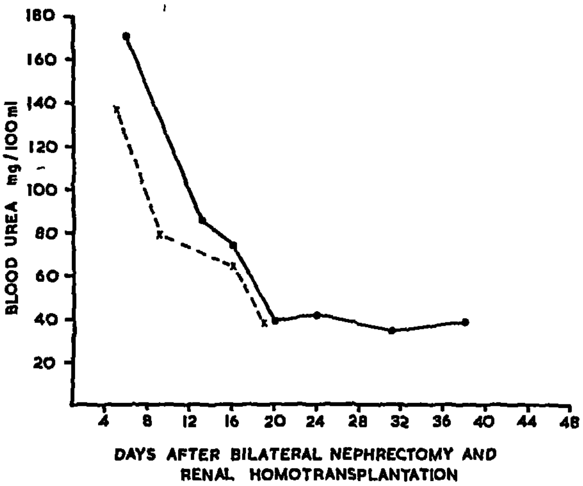

Fig 3—Blood-urea levels in dogs surviving 21 and 47 days after bilateral nephrectomy and renal homotransplantation

which had been off 6-mercaptopurine for six days owing to leucopænia there was evidence at 12 days of cortical cellular infiltration, which was regarded as a mild homograft reaction

In a second series of experiments, in order to assess the function of the transplanted kidney, bilateral nephrectomy was performed at the same time as the renal homotransplantation The dosage of 6-mercaptopurine was 5 mg per kg intramuscularly for the first 2 days, 2 5 mg per kg intramuscularly for the next 4 days, and then 2 5 mg per kg daily by mouth except when the total white-cell count fell below 5000 per c mm

Several dogs on this regime died with oliguria 4–6 days after operation No homograft reaction was found in the kidneys Their death was thought to be due to a vicious circle of primary anuria, uræmia, and vomiting, leading to prerenal uræmia

The two dogs surviving this critical period died of pneumonia, on the 21st and 47th days after operation. In the longer survivor the liver was bile-stained and showed intralobular biliary stasis, its parenchyma was not necrotic In both dogs the grafted kidney was normal macroscopically, and microscopy revealed no evidence of the homograft reaction (fig 2), although there were areas of hæmorrhage in the kidney that functioned for 21 days Both animals were passing concentrated urine up to the time of death The blood-urea levels are shown in fig 3

In an attempt to prevent the early deaths, the procedure was further modified by performing only unilateral nephrectomy at the time of renal transplantation, leaving removal of the second kidney till a later date

DISCUSSION

In dogs first-stage renal homografts usually cease to function after 4–8 days, showing massive cellular infiltration The longest periods of function in four recent series are 11 days,[2] 12 days,[3] 14 days,[4] and 20 days[5] In an irradiated dog a renal homograft has survived 49 days,[6] and the kidney was found to be normal microscopically

My observations with 6-mercaptopurine suggest that this drug can modify the rejection of renal homografts in dogs It could have advantages over total body irradiation in being less hazardous, and possibly less crippling immunologically, though it seems to increase liability to infection and can cause hepatic biliary stasis[7] Its use might thus offer an approach to renal homografting in man, especially in chronic uræmic patients in who homograft rejection is already depressed[8]

The effects observed could be explained either by non-specific cytotoxic action of the drug on the immu system, or by a true specific production of immu tolerance This problem is being investigated

I am much indebted to Prof D Slome for his help and encourag ment and to the council of the Royal College of Surgeons for provi ing facilities, materials and technical assistance at the Buckst Browne Research Farm, where this work was done I am al grateful to Mr J P Hopewell and Dr K A Porter for their guidan and advice

Burroughs Wellcome & Co provided the 6-mercaptopurine, whi was prepared for me in the dispensary of the Royal Free Hospit The histological sections were made in the hospital's departme of pathology

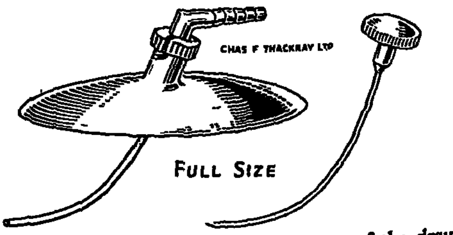
CANNULA FOR TREATMENT OF SUBDURAL EFFUSIONS IN INFANTS BY CONTINUOUS DRAINAGE

Subdural effusion is fairly common in infancy and causes high morbidity if neglected Early treatment must be unde taken to avoid restriction of brain expansion and to preve impairment of mental development It is important, therefor to remove the fluid which collects in the subdural space

When the effusion is a true hæmatoma one or two subdur taps usually suffice But if the effusion is a subdural hygroma after subdural tap the fluid rapidly collects again from th subarachnoid space, being pumped up by leakage *Henc* continuous drainage may be necessary to allow adhesiv *obliteration of the subdural space*

The immediate evacuation of large subdural effusions i *infants carries a high mortality an early, but gradual,* release o pressure is preferable The practice in some clinics is to per form subdural taps daily on alternate sides, removing 10–15 ml of fluid each time If the fontanelle quickly becomes tigh again, or, if the baby's general condition is poor, it may b necessary to tap more frequently For many years Prof Norman Dott of Edinburgh has advocated a system of continuous drainage of the subdural space

Continuous drainage avoids the need for multiple punctures —which can lead to infection—and reduces the distress caused to the child and the possibility of bleeding after frequent needling By adjusting the height of pressure of the drainage system the rate of evacuation can be controlled, thus permitting slow progressive drainage over days, and facilitating the adhesive obliteration of the subdural space



With this method of treatment, operative excision of hæmatoma *membrane will rarely be needed (Such membrane,* composed of fibrin, may form on the undersurface of the dura and become a " space-occupying lesion ")

The requirements of a continuous drainage cannula are

1 It should be of reasonable calibre to permit free drainage without blockage

2 With its attendant fine trochar it should easily enter the subdural space with a clean puncture and negligible trauma

3 It should fit snugly and firmly to the scalp with the minimum of dressings Unless it is secure, its movement may cause further bleeding in the subdural space

4 The connection from the cannula to the drainage tube leading to the collecting-flask must be securely locked, loose attachments which are liable to come adrift lead to unsterile attempts at reconnection, with the possibility of infection

The present cannula meets these criteria. The trochar and cannula are made of stainless steel and are size 18 or 19 B W G The cannula is attached to the scalp shield at an angle of 30° This allows it to drain the subdural space while the shield is firmly applied to the scalp The fixity of the shield minimises movement of the cannula, which cannot " wiggle " or " move " inside the skull The connecting link to the cannula is a 'Record' pin locking movement which affords a firm connection and from which the rubber drainage tube leads to a conical half-pint collecting-flask. This flask is held in place at the end of the cot with a double clamp which can be raised or lowered, thus altering the head of pressure and enabling the rate of escape of the effusion to be controlled

Procedure

The standard procedure for subdural tap in infancy is followed The crown of the infant's head is carefully shaved and cleansed and held firmly in a sterile towel by an assistant. Professor Dott tells me that he has found the following cleansing technique satisfactory for preventing the infection which may arise with indwelling drainage tubes in the subdural space

" The scalp is washed carefully with cetrimide (' Cetavlon ') and rinsed with saline While it is still moist ' Polybactrin ' antibiotic spray is applied to the scalp A blob of ' Cicatrin ' (antibiotic cream) is applied to the scalp on the site where the cannula puncture is to be made In addition to its valuable antibiotic content the lubrication effect of the cicatrin cream makes for a clean and easy puncture "

A thin gauze dressing 2 or 3 mm. larger in diameter than the scalp shield is pierced centrally by the trochar and cannula and slid into position on the under-surface of the shield. The subdural space is then punctured and the trochar is immediately eased back, but it is not withdrawn, lest there should be a sudden uncontrolled release of the subdural effusion. The cannula is then gradually and gently slid into the subdural space, with the shield resting gently and evenly on the scalp The trochar is withdrawn and the connecting-piece is locked in position, having already been connected by the rubber tube to the collecting-flask. The patency of the drainage having been established, the cannula is firmly fixed in position by placing four pieces of $^1/_2$-in. ' Sleek ' adhesive a few inches in length across the shield, crosswise, after cleansing the scalp with ether In practice, even if the infant is restless, the cannula is very unlikely to work loose or disconnect, and routine nursing and feeding can be followed without hindrance

The cannula should not be left in any one puncture site longer than three days A few fresh punctures can of course be made, the complete drainage apparatus having been resterilised before reconnection, but the duration of continuous external drainage should be limited to two or three weeks at most For the very occasional case where fluid is still collecting after three weeks, the extra-light-opening-type of Spitz-Holtzer valve might perhaps be used as a means of closed internal drainage

I am grateful to Prof Norman Dott and to Mr W R Henderson, and also to Mr Lockhart, of Messrs Charles F Thackray & Sons, Leeds, who manufactured the cannula

Reviews of Books

Human Biochemical Genetics

H HARRIS, M.D , reader in biochemical genetics, London Hospital Medical College London Cambridge University Press 1959 Pp 310 37*s* 6*d*

DURING the past three years there has been a flush of books, articles, and symposia on various aspects of human biochemical genetics This is no more than it should be " From being an obscure subject, supposedly only pursued by academically minded cranks and of little significance in therapeutics, the study of inborn metabolic errors is becoming a very important branch of medicine " so wrote Penrose in 1957 This excellent book, written by one of the leaders in the field, has come at an opportune moment. The literature has been scattered among the biochemical, medical, and genetical journals, so that many doctors have been slow to grasp the enormous impact of this subject on clinical medicine. Already, however, many of the larger medical schools, in the admittedly specialist-minded United States, are pondering the establishment of departments of medical genetics

The book begins with an introductory account of the principles of human population genetics Disturbances of aminoacid metabolism, carbohydrate metabolism, human hæmoglobins, blood-group substances, and plasma-proteins are among the subjects discussed informatively They are, moreover, discussed not from the viewpont, too often adopted these days, of metabolic defects which " happen to be inherited " but from the more sophisticated viewpoint of problems in classical biochemical genetics Inevitably the book reflects the author's interests and experience and would not claim to be encyclopædic.

The chapter on the human hæmoglobins is as up to date as possible in a rapidly moving subject. Dr Harris properly lays emphasis on the extraordinary fact that the substitution of a single aminoacid (valine for glutamic acid, for example) in a hæmoglobin molecule consisting of approximately 560 aminoacids can result in the difference between normal and sickle-cell hæmoglobin—between health and disease Unquestionably, many aspects of this section will need to be rewritten and enlarged in future editions The aminoacid sequence in the anomalous peptides of hæmoglobin C and S (illustrated in fig 46) will have to be revised in the light of Ingram's recent work. The details are less important, however, than the general concepts, which are admirably emphasised

The chapter on blood-group substances is an extremely clear exposition of a difficult subject. The section on inherited serum-proteins, however, is a little sketchy There is no mention of the inherited variation in serum-albumin, first described in 1957, in which serum-albumin is present in two distinct molecular species (" double albumin "), nor indeed of certain other inherited serum-proteins, some of which have been recently described by Dr Harris Unavoidable delays in publication are no doubt largely responsible The beta-globulin variants are now recognised as transferrins, and the account of inheritance of the gamma-globulin groups will have to be expanded considerably in later editions The current and lively topic of the genetic aspects of antibody formation is not discussed, and surprisingly no reference is made to the contributions of Beadle and Tatum, whose work in biochemical genetics, albeit in species other than man, has been outstanding Dr Harris has remained strictly within his title, and some readers would perhaps have liked at least an occasional reference to species other than man

Nowhere are the disciplines of biochemistry and clinical medicine more closely linked than in the conditions discussed here, and we hope this book will reach the desks of all biochemists concerned with the teaching of medical students The author might have permitted himself the luxury of a little more speculation he does not, for instance, discuss in any detail the possible ways in which alteration of the base sequences in D N.A. can give rise to altered proteins We find little or no mention of coding mechanisms, soluble R.N.A , or ribosomes, but these are small points Only a few misprints were noticed in a book which successfully combines sound production with modest price

There is no doubt that this is the best book on human biochemical genetics available today Dr Harris is to be congratulated on a much needed work well done it can be warmly and unreservedly recommended

Water Supply for Rural Areas and Small Communities

E G Wagner, chief engineer, division of health and sanitation, Institute of Inter-American Affairs, Rio de Janeiro, J N Lanoix, sanitary engineer, division of environmental sanitation, W H O, Geneva World Health Organisation Monograph Series no 42 Geneva W H O (Obtainable from H M Stationery Office, P O Box 569, London, S E 1) 1959 Pp 340 35*s*

Those who first urged a clean water-supply may have been stirred by irrational emotions derived ultimately from J J Rousseau, but they did as much for the public health as all the bacteriologists put together We turn on the tap and accept their bounty without question To us typhoid and other water-borne infections are no more than rare curiosities Most of the world's inhabitants are, however, still countrymen who lack piped water, main drainage, and electricity—and of these the first is the most important by far One of the happiest pages in the history of our rule in India is the effort made to give the villager a "safe" well, and now almost everywhere clean water has a top priority

This book is a model for what such publications should be It is practical and inclusive and cheap In it anyone from Iceland to Peru can find plain directions for the choice, impounding, and purification of any sort of available water he can get some idea of the cost of building and working the supply and the staff which will be needed The book may emanate from Geneva, but the authors know from personal experience that most wells are still dug with pick and shovel or mattock and the earth removed in a basket on a rope

The book fills a need even in this country Few medical officers of health have had the opportunity to learn much about emergency water-supplies, and circumstances could arise in which these would have to be improvised amid wreckage and confusion

J M Charcot, 1825-1893

His Life—His Work Georges Guillain, M D Edited and translated by Pearce Bailey, PH D, M D, director, National Institute of Neurological Diseases and Blindness, Bethesda, Maryland London Pitman Medical Publishing Co 1959 Pp 202 50*s*

Those Parisians who lived within the ramparts of the old city during the middle of the sixteenth century were so often disturbed by violent explosions in the royal arsenal that they petitioned Louis XIII to store his gunpowder elsewhere In 1565 he acceded to their request, and erected another arsenal on the opposite bank of the Seine In later years these buildings were much enlarged, and came to be used as an infirmary, at first for destitute women and prostitutes, and then for the chronic sick, the crippled, and the insane At times this "grand asylum of human misery" housed as many as 8000 patients, some under appalling conditions The work of such men as Pinel, Magendie, and Cruveilhier did much to ameliorate and to enhance the reputation of the Salpêtrière (as the institution continued to be called) But it was the appointment, in 1862, of Jean Marie Charcot, as its chief of the medical service, which was destined to make it a Mecca of doctors the world over

A modern physician, as Professor Guillain points out, finds it hard to appreciate the debt neurology owes to Charcot When he began his work at the Salpêtrière, scarcely anything was known of the pathology of nervous disease the methods of clinical examination in common use were rudimentary and ineffective and such terms as "tremor" and "paralysis" were regarded as constituting a sufficient diagnosis in themselves One half of this book describes in considerable detail the publications and researches by which Charcot raised the whole status of our knowledge of diseases of the central nervous system the other is devoted to a personal biography Though its author never met Charcot, he is senior enough to have known many of his pupils and friends, and his book is an important contribution to our knowledge of a man who has not hitherto received from biographers the attention he deserves, as the Father of Neurology

Recent Progress in Psychiatry

Vol 3 Editors G W T H Fleming and A Walk London J & A Churchill 1959 Pp 397 42*s*

This volume is the third in the deservedly well-known series sponsored by the Royal Medico-Psychological Association (others appeared in 1944 and 1950) and the contributions live up to a distinguished tradition Since many relevant advances have been made in related disciplines, clinical chapters are rather fewer, and the condensation of a vast area (nearly 2000 references are covered) makes for hard reading in places, although Prof Alexander Kennedy and Dr F J Fish, for example, writing on addiction, and Dr R Gibson on mental deficiency, show that brief but extensive surveys can be both scholarly and easy to read Other topics authoritatively covered are surgical treatment (Mr M A Falconer and Mr Peter Schurr), child psychiatry (Dr Kenneth Cameron), major crime (Dr Jonathan Gould), and genetics (Dr Valerie Cowie and Dr Eliot Slater) More abstruse are biochemistry (Dr Derek Richter), enzymes (Dr Gould), the physiology and pathology of cerebral structures (Dr T P S Powell, Dr J A N Corsellis, Dr Alfred Meyer, Dr R M Norman, and Dr Henry Urich), cybernetics (Dr W Ross Ashby), and personality testing (Prof H J Eysenck) A name index, an ampler subject index, and prompter publication (the most recent papers quoted are 1956) might be possible for the next volume

In his introduction Dr Fleming declares

> "*Modern psychiatry is passing through a period of apparent* change The law relating to mental illness has come under considerable criticism, some of it from the unstable and hysterical This has led to changes in administrative outlook which are certainly not always in the best interests of the patient, his relatives, or the public, but bolster up the ego of the inferiority unconscious psychiatrist Amongst the inexperienced there is an impression that what they are doing has never been done before, and they either make no attempt to ascertain how much was done twenty and more years ago, or turn a deaf ear and a blind eye"

If one of the objects of this sharp passage is to restrain over-enthusiastic zeal for reform it should surely have been more sympathetically worded As it stands it can hardly fail to sour the atmosphere what is needed by young and inexperienced enthusiasts (of whom there seem to be too few by our reckoning) is guidance and encouragement

Fundamentals of Gynecology

Samuel J Behrman, M S, M R C O G, F A C S, associate professor, obstetrics and gynecology, University of Michigan Medical School, John R G Gosling, M D, assistant professor, obstetrics and gynecology, University of Michigan Medical School New York and London Oxford University Press 1959 Pp 416 76*s*

This new book by two American teachers is based on the lecture course in gynæcology at the University of Michigan Medical School and is designed for senior students and general practitioners It gives a lucid, well-ordered account of modern gynæcology, in which the British viewpoint is well represented The general layout of the material is sound and the exposition clear The publishers deserve special credit for the excellent production

Each chapter is a short, balanced, and authoritative monograph on some division of gynæcology At the end of every chapter there are appropriate references, British and American, to which the reader may turn for more detailed information. The chapters on Virilism and Intersexuality in the Female, Endometriosis, and Hydatidiform Mole and Choriocarcinoma are especially valuable, and the whole section on malignant disease is very effective, though conceivably it might be improved by more detail about the place of cytology in the early diagnosis of cancer of the cervix The text is well illustrated by diagrams, photographs, and drawings, but occasionally the photomicrographs are too small for detail to be seen

THE LANCET
LONDON 20 FEBRUARY 1960

The Report

THE Royal Commission remark ruefully that their task was expected to be simple but proved otherwise. Though they have listened patiently to a great many suggestions for improving the National Health Service, they have had to resist any temptation to solve all its problems. But their recommendations, though mainly monetary, reflect well-founded and friendly opinions, on the profession and the service, for which we can be thankful.

Some things that people told them, they do not accept: they are not bothered about medical emigration, for instance, or a decline, so far, in recruitment. They flatly declare, too, that remuneration can no longer be governed by the Spens reports. As basis for their own conclusions they have collected a mass of new information about medical and other incomes, from which they conclude that medical earnings are too low. But they also add opinions which reflect their experience in other branches of life—notably that the young doctor is relatively underpaid, that the range of incomes should be wider, and that special distinction—in general practitioners as well as in consultants—needs financial recognition. Promotion and differential remuneration are never quite equitable, in any organisation, but on the whole the system works. The Commission find it hard to believe that Medicine alone has a complete lack of "that selective ability which is exercised in practically all other occupations." Not without humour, they suggest that their proposed fund of £500,000 a year, set aside for recognising distinguished general practice, shall revert to the Exchequer if not used.

For consultants, distinction awards should, they think, be higher but limited in number, and substantial rises of pay are proposed for all hospital staff. Leaving to the Platt Working Party the question of hospital grades, the Commission do little to solve the registrar problem except that they leave senior registrars on a rising scale for a longer time. Their most important change of relativities lies in the higher pay for registrars, senior house-officers, and particularly house-officers, who "have been greatly underpaid both in relation to their seniors and in relation to what is paid to comparable people in other professions." Whereas elsewhere the Commission's rates are a little lower than those suggested by the British Medical Association, for the house-officer they are higher. Another recommendation designed to help peripheral hospitals would entitle these to pay an additional £100 a year to junior staff.

The Commission's proposals for general practice are preceded by a masterly review of the practitioner's present situation. They would retain capitation fees, and the pool, and, though the amount to be put into this for each doctor would be raised only to £2425, they say that, with changed methods of calculating the pool, this would mean an average increase of £450 over 1955–56. Professor JEWKES, in an impressive memorandum of dissent, argues that this increase, like that suggested for part-time consultants, is too low either to restore confidence or to ensure recruitment: he says that unless practitioners' remuneration is now raised by at least 30% over that ruling in 1955–56, their position will have deteriorated during the decade in relation to that of other people. On reduction of the maximum list the Commission do not commit themselves: whatever is decided about this, they are anxious that a wide range of incomes shall be achieved—the distinction award being one possible means. "We do not believe that constant striving for increased income is or should be the main incentive to good general practice, but at the same time we think it must be discouraging both to existing doctors and to potential recruits if a really first-rate practitioner has so little prospect of earning more than one who is merely satisfactory." Again urging better pay for the young, they are generous to the trainee assistant. Other assistants, they hope, will benefit too, though less directly.

Even more important than what is paid in 1960-63 is what happens later. We are all painfully familiar now with the type of Government economy which asks disproportionate sacrifice from people who happen to be paid from public funds, and we are grateful both for the Commission's acid statement that "doctors and dentists must have some confidence that their remuneration will be settled on a just basis" and for their declaration that "doctors and dentists in the public service should not be used as a regulator of the national economy." To review major issues periodically, the Commission propose a standing Review Body, of seven independent persons, to advise the Prime Minister (Professor JEWKES, who evidently shares our wish for more strategic planning of the Health Service, would like to see this develop into an Advisory Council.) The Commission remark, again rather pointedly, that the recommendations of the Review Body "must only very rarely and for most obviously compelling reasons be rejected." Their request that £11 million shall now be paid to general practitioners, and £9 million to hospital doctors and dentists, in respect of the time elapsed since the inquiry began in 1957 is evidence that they do not regard the profession's repeated protests as baseless. We earnestly share their hope for an end, once for all, to the damaging disputes of the past.

Hæmorrhoids

"NATURE is not infallible," Saki's major observed, "but she usually abides by her mistakes" Whether they are inborn flaws or signs of imperfect adaptation, a host of minor ailments that beset us after the age of twenty seem to support his contention Hernias, varicose veins, slipped discs—all carry an excellent prognosis for life and a tolerable one for comfort, but the chances of complete cure are often remote By most published accounts hæmorrhoids—perhaps the most important member of this group—are the exception, for they are said to be eminently curable But are they in fact? The truth about hæmorrhoids is not easily discovered to many doctors they remain an unexciting and to most patients a faintly embarrassing complaint And yet these patients form a large proportion of chronic bleeders, and chronic bleeders, with their lowgrade but intractable iron-deficiency, should be one of our pressing concerns Neither ill nor well, unable to cope with their work and incapable of enjoying their leisure, these men and women become, in the prime of their lives, a trial to themselves and an unrecognised burden on the community They also become the worst of patients—truculent in seeking advice, erratic in following it, always ready to take their own discharge once in hospital It is hardly surprising that many are fobbed off by their doctors with iron—any old iron—at an early stage of their illness and thus find themselves launched on a vicious circle of bleeding, iron-deficiency, increasing istrogenic constipation, more bleeding, and worse iron deficiency Even spontaneous remissions are not an unmixed blessing, for they promote indiscriminate claims made for a bewildering variety of patent "anti-hæmorrhoidals"—some so extravagant that they could hardly be expected to sell were prospective buyers' critical faculties not blunted by a hæmoglobin of 60%

The rational management of hæmorrhoids, like that of most common but not life-threatening illnesses, calls for a compromise between the ideal and the workable To preach prophylaxis, tracing back the condition to bad bowel-habits inculcated in childhood, is hardly practical, nor is it realistic to suggest (as some textbooks do) that every case of rectal bleeding should be investigated not only clinically but also hæmatologically and radiologically Isolated episodes in young people are extremely common and usually of no significance intelligent assessment of the history and a brief general and careful rectal examination is all that they require If the bleeding recurs, however—and before embarking on surgical treatment—at least two common underlying causes must be excluded The spectre of hæmorrhoids masking carcinoma of the rectum so effectively haunts most newly qualified doctors that their elders are more likely to offend Less widely appreciated is the common association between non-specific proctitis (with or without hæmorrhoids) and rectal bleeding, and, even when remembered, the diagnosis may tax the most experienced

When a serious underlying disease has been excluded, a course of injections can be confidently recommended for grade-1, grade-2, and even some grade-3 hæmorrhoids—provided that emphasis is laid on the "course" Proctologists often deplore that the average patient, delighted by even a temporary respite, is not urged by his general practitioner to attend a second and third time, but proctologists themselves are not entirely blameless In skill, hygiene, and efficiency the special clinics which are now run by most hospitals have been a great advance on the old system of seeing rectal cases in general surgical outpatients, but all too often increasing efficiency generates an unwholesome conveyor-belt spirit Clad in gaily coloured but ill-fitting dressing-gowns patients are marched by sister into grim little cubicles, instructed to hop on a couch, and reduced into a position which can demoralise the toughest, and after an anxious wait (which might have served as RODIN's inspiration for his *Danaïde*) they may find themselves impaled on a sigmoidoscope without having set eyes on the surgeon Inflated, injected, and thoroughly intimidated, most of them are yet grateful for the relief afforded by the treatment, but their disinclination to attend again is not perhaps to be wondered at Serious complications from injections are oddly few potentially perhaps the gravest, as also the most insidious, is hepatitis from intravenous phenol

For hæmorrhoids which recur after two or three courses of injections and for most grade-3 cases well-conducted hæmorrhoidectomy is thoroughly worth while, but what a "well-conducted hæmorrhoidectomy" means has been disputed almost since the dawn of surgery The results from the clamp-and-cautery operation, as described by FARQUHARSON,[1] and from the St Mark's Hospital dissection-ligature operation [2] have been compared by CORMIE and MCNAIR [3], and their findings shed light on the late results of surgical treatment in general 163 consecutive patients who had been treated in one unit of the Edinburgh Royal Infirmary by one of the two operations were circularised by letter and 100 were available for reassessment After an average of four and a half years only 65 could be classified as "excellent" results, but the criteria were strict, and "no less than 94 of the 100 patients were either cured or were improved to the degree of suffering from only minor occasional symptoms All these patients were in no doubt about the merits of the operative treatment and many expressed the wish that they had come at an earlier date and so saved themselves many years of discomfort" On the other hand, it is perhaps not unreasonable to assume that (apart from 10 who had died from other illnesses since the operation) the 53 who could not be traced or who could not attend may have included a larger proportion of dissatisfied patients, nor would a five-year follow-up include late recurrences Immediate complications were few after either operation only 1 patient had a hæmorrhage, and this responded to conservative measures

[2] Milligan, E T C, Morgan, N C, Jones, L E, Officer, R *Lancet*, 1937, ii, 1119

[3] Cormie, J, McNair, T J *Scot med J* 1959, 4, 571

(Hughes[4] reported 3 cases of this, potentially the most serious, complication in a series of 221 cases) Postoperative retention, regarded by some as almost inevitable, was rare in both groups, but pain and discomfort were strikingly less after the clamp-and-cautery procedure Cormie and McNair recognise that this may reflect small individual differences in technique (such as the use of a flatus tube instead of petrolatum-jelly on soft dressings), but conceivably the linear scars of the cautery are in themselves less painful than the raw surfaces left after dissection and ligature Of the late complications stricture-formation is the one most dreaded, and, especially when not recognised in time, it can indeed be a disaster In the Edinburgh series mild stenosis was slightly commoner after the St. Marks' Hospital procedure, but such stenosis can follow any operation (and even misplaced injections) and probably results from some error in technique The need for a "tidy" end-result is doubtful skin-tags are usually symptomless but commoner when the cautery has been used Chronic fissure-in-ano—a far more troublesome sequel—appears to have developed in about the same proportion of the two groups

What emerges from the Edinburgh and similar surveys is that, good though the results are, there is scope for improvement at all stages of the illness and all levels of its management. Hæmorrhoids are said to have been one of the three essential adjuncts and afflictions of the successful Victorian physician A paunch was his hallmark of well-merited affluence, baldness gave him an air of experience and wisdom, and hæmorrhoids ensured a look of constant anxiety We can pride ourselves of having shed both the substance and the meaning of the first, we are casting doubt on the interpretation of the second, but we remain faithful to the third Hæmorrhoids is still a disease of the professional classes it deserves the interest—but is often accorded the neglect—of a doctors' ailment.

Fifteen Years of Antibiotics

In 1945 the only antibiotic available for systemic use was penicillin today there are about fifteen How then do we stand? So wide a question demands a comprehensive answer, and we are fortunate that this has been given in a valuable issue of the *British Medical Bulletin*,[5] edited by Prof L P Garrod, which contains fifteen articles by eighteen other experts If all users of antibiotics read and understood these articles there would surely be a great increase in the efficacy of antibiotic treatment combined with a striking reduction in the number of patients given antibiotics, the number of undesirable complications, and the number of antibiotic-resistant strains of bacteria It is not possible for anyone—or any Government agency—to utter a series of commandments on the use of antibiotics, because there are important aspects of the subject about which it is not yet possible to dogmatise But clearly an antibiotic is often given without a clear enough reason in the mind of the doctor prescribing it True, what begins as a minor illness not apparently requiring an antibiotic may develop into something more if it is not treated, whereas it may respond admirably if it is treated As Garrod and Scowen[6] say "Each case must be judged on its merits, but if these are deliberately assessed, and if the treatment has an explicit rational basis, really indiscriminate use will thereby be excluded"

Clinicians are not slow to emphasise that they know of cases in which a laboratory report on the sensitivity or resistance of an organism to a particular antibiotic did not correlate well with the patient's response to treatment with that drug This observation is often enough correct, and there are at least seven possible explanations for it (1) an effective antibiotic may be unable to reach a sensitive organism (in dead tissue or pus, for example), (2) if infection is secondary to obstruction or stasis, in the urinary tract or elsewhere, the effect of any chemotherapy will be only temporary unless the underlying condition can also be relieved, (3) special conditions may be needed for an antibiotic to act (streptomycin, for example, is about 50 times more active in an alkaline than in an acid urine, whereas penicillin and chlortetracycline are more effective in an acid medium), (4) the antibiotic may be diluted beyond the point of effectiveness (a mischance especially probable in urinary infections because these patients are traditionally urged to drink all they can, whereas restriction of fluids for a time is necessary to secure the greatest possible concentration of the drug in the urine), (5) resistance of an organism to a particular antibiotic, reported by the laboratory, does not hinder natural recovery from an infection which would resolve without chemotherapy, (6) the sensitivity of the culture tested in the laboratory may differ from that of the organism in the patient's tissues, and (7) circumstances may sometimes allow the attainment of concentrations of antibiotic in the tissues greater than those normally to be expected Despite discrepancies of this kind, Gould[7] leaves no doubt about the important part which the laboratory should play in assisting chemotherapy, for clinical diagnosis is not often a dependable guide to the identity and antibiotic sensitivity of the infecting organisms Further, the laboratory may help in measuring the efficacy of treatment and aid the clinician in his decision when he may safely stop it

Lowbury,[8] discussing possible measures to combat the emergence of drug-resistant pathogens, evaluates discriminating restraint in the use of antibiotics, prevention of hospital infection, well-chosen combinations of drugs for a few special infections, and agreed schemes for the use of antibiotics in rotation—a change being made as soon as, or preferably before, drug-resistant strains of bacteria appear He rates attempts to prevent cross-infection as probably the most important, but finds better hopes in some of the newer antibiotics than seemed at all likely a few years ago Some of these new drugs are too toxic for parenteral use, but others are not

[8] Lowbury, E J L *ibid* p 73

—although, in general, the treatment must be conducted with a sharp watch for toxic signs and a resolve not to overdose the patient or unnecessarily prolong the treatment Usually combinations of drugs are needed for the treatment of tuberculosis and subacute bacterial endocarditis caused by enterococci **Barber** et al[9] showed that the combination of novobiocin and erythromycin apparently prevented the emergence of resistant strains, whereas the combination of chloramphenicol and erythromycin should be avoided because of cross-resistance between the two drugs Obviously, the use of antibiotics in combination requires much more critical thought and study than it has yet received It is a relief that the uncritical enthusiasm for combinations which was notable a few years ago appears to have abated

The enterprise of those who have pioneered the development of antibiotics has been notably supplemented, to the benefit of all, by the outstanding efforts of the pharmaceutical industry Understandably the industry wishes to have a reasonable financial return, but probably all of us, including the industry, would be happier if the over-enthusiastic reports of uncritical users of some of the new preparations were carefully, realistically, and even sceptically assessed before they were allowed to exert any great influence on sales policy

Annotations

ESCHERICHIA COLI IN PETS

A few weeks ago we called attention to the dangers of keeping dogs, and indeed of having anything at all to do with them[10] Now a further possible hazard has been revealed Mian,[11] working in Michigan, examined 321 household pets and found serotypes of *Escherichia coli* known to be associated with infantile enteritis in 14% of dogs and 8% of cats Furthermore in one instance he detected the same serotype (O 55 B5) in a child with diarrhœa and in a dog in the same house (the possibility that the baby infected the dog does not seem to have been considered)

Knowing the almost indecent intimacy which many pet-lovers allow their furry friends, we are not surprised, and yet we feel bound to accept this warning with some caution There is no longer any doubt that certain serotypes of *Esch coli* cause enteritis in children under 2 years and occasionally in older people, but the same serotypes are also found not uncommonly in apparently healthy persons of all ages No-one has brought forward very convincing evidence that babies are infected by their mothers or vice versa " Scouring " in calves deprived of maternal colostrum is also caused by certain serotypes of *Esch coli* Some of these are identical with those implicated in human disease, and it was thought at one time that cow's milk was an important source of human infection In recent years, however, the serotypes prevalent in calves and babies have not been the same, and indeed one of the most interesting things about these diseases is the changes over the years in the types most commonly associated with human and bovine disease In this country types O 55 and O 111 have largely given way to O 26 and O 119 in babies, while in calves O 78 and O 137 have displaced O 9, O 26, and O 35 Other serotypes—some shared with humans and calves—have been found to cause enteritis in lambs and various ailments in piglets[12] It is a reasonable guess that all young animals are liable to these infections, but whether the disease in one species has any relation to that in another we do not yet know Incidentally some of these pathogenic serotypes have been found in well-water

This epidemiological problem is confusing Interest in the enteroviruses has encouraged the idea that enteric disease in the young is due to one or more viruses and that the " pathogenic " serotypes of *Esch coli* are normal inhabitants of the upper bowel flushed down by viral diarrhœa (In current medical conversation " virus infection " is likely to mean " a disease of uncertain ætiology ") Yet recognisable enteroviruses are rarely if ever found in patients with diarrhœa who are excreting any of the specific serotypes of *Esch coli*[13] For the moment we must accept that these are the cause of the disease, and, yet clearly the epidemiology of " coli enteritis " differs quantitatively if not qualitatively from such infections as typhoid fever or Sonne dysentery The number of symptomless excreters—" carriers " begs too many questions—is far greater, and yet when the disease spreads in a children's ward it is highly infectious and persistent In some well-run hospitals the disease is almost always present in others, a few miles away, only occasional sporadic cases are seen

We hope that others will repeat Mian's work and compare their findings with those of the local hospital The origin of single infections is always obscure, and domestic pets are as likely a source as any It is true that not much has come of the observation that about 3% of dogs carry *Salmonella spp*, but perhaps this lead has not been pursued with enough vigour At any rate these findings give the family doctor yet another reason to discourage dogs from sleeping on beds or licking the baby

AUTOMATION

Automation—a threat to the community or a panacea? Whatever its advantages it clearly raises problems, including problems of mental health, and W H O has published the report of a study group which considered this aspect[14] The study group point out that automation may be broken down into three overlapping types " transfer automation " of the assembly-line type now long familiar, " control automation " based on automatic feedback of information into a mechanical system, and " computer automation ", the most revolutionary, used most commonly in the recording, coordination, and analysis of information for administrative purposes Automated work may affect the functioning of operators, and therefore possibly cause mental ill health, through increased responsibility without action to provide relief, through the need for close attention without adequate motor discharge, through solitariness, and through " depersonalisation " The need to react almost instantaneously to alarm signals is a particular strain, which may be alleviated by rational grouping of indicators and the presentation of useful information only Adequate changes of position and good general environmental conditions are also important The effects of excessive isolation and absence of social contact are compared with those of " sensory deprivation ", which may be profoundly disturbing[15] These effects may be avoided by reducing noise level, placing machines suitably, shortening shifts, increasing breaks during working hours, and a system of flexible rotation

[14] Mental Health Problems of Automation, *Wld Hlth Org tech Rep Ser* 1959, no 183 Obtainable from H M Stationery Office, P O Box 569 London, S E 1 Pp 30 1s 9d

The study group stresses that automation is likely to bring important advantages It should enable working conditions to be improved, and in the long run lead to reduction of working hours and an increase in the trend towards better wages People should not be confronted with the new type of life associated with automation without adequate information and education, this is particularly important for those holding key positions There is still much to be learned about the impact of automation on the individual and society

BLOOD-AMMONIA AND EMPHYSEMA

Raised blood-ammonia levels may be found in association with advanced liver disease, and they have also been observed in states of shock,[16] congestive heart-failure,[17-19] and diabetic coma [20] Recently Dutton et al [21] reported high blood-ammonia levels in patients with chronic pulmonary emphysema unassociated with congestive heart-failure, and they now amplify [22] their original observations They studied 34 patients with chronic pulmonary emphysema, none of whom had clinical evidence of congestive heart-failure or liver disease and none of whom were receiving drugs known to influence blood-ammonia levels Bromsulphalein tests of liver function were carried out in 28 of these patients, and comprehensive tests of lung function in 12 The mean venous blood-ammonia value for the 34 patients with emphysema was 52 μg per 100 ml , and that of a control group of 37 patients was 26 μg per 100 ml , the figure for the emphysematous subjects was thus significantly higher ($P < 0\,01$) The 12 patients whose lung function had been intensively studied were classified into three groups according to the results of blood-gas analysis after standard exercise [23] in group 1 arterial oxygen saturation was above 92%, in group 2 arterial oxygen saturation was below 92% and arterial CO_2 tension below 48 mm Hg , and in group 3 arterial oxygen saturation was below 92% and arterial CO_2 tension above 48 mm The blood-ammonia levels were normal in the 3 patients in group 1, and raised in the 7 patients in group 3, they were normal in 1 of the patients in group 2 and elevated in the other

Dutton et al do not find it easy to account for the abnormal blood-ammonia levels in these patients with pulmonary insufficiency A rise in blood-ammonia may be due to impaired ability of the liver to convert ammonia to urea, but no evidence of liver disease was detected Portapulmonary and thoracic portacaval venous anastomoses may exist in the absence of portal cirrhosis,[24] but Dutton et al consider it unlikely that blood would have passed into the systemic circulation through such channels even if they were present in their cases, because of the raised intrathoracic pressure associated with the pulmonary disease Since muscle activity has been reported to raise blood-ammonia levels,[25] it seemed possible that increased respiratory work might explain the rise in the emphysematous patients, but the absence of any rise of blood-ammonia in 2 healthy subjects who increased their ventilation to many times the normal value lent no support to this hypothesis On the whole, they think the likeliest explanation is that chronic hypoxia impairs the ability of the liver to metabolise ammonia, and that this defect is not necessarily reflected in the results of the bromsulphalein test Hyperventilation observed in patients in early hepatic coma has been thought to be due possibly to the action of high blood concentrations of ammonia on the respiratory centre [26 27], and Dutton et al suggest that in pulmonary emphysema with carbon-dioxide retention a high blood-ammonia may be a factor additional to arterial hypoxia in stimulating respiration

SCHOOLS AND INFECTIOUS DISEASES

The bedevilment of medicine by ex-cathedra statement has seldom been better illustrated than by W H O examination [28] of current practice in excluding childre from school because of infectious disease This survey based on legislation and recommendations in one Asia three Australasian, eight European, two African, and fo American countries or States Surprisingly no referen is made to *Control of Communicable Disease in Man*,—th official report of the American Public Health Association It is understandable that different countries issue different rules which vary widely, but, to add to the confusion, individual cantons in Switzerland and States in America and Australia have their own laws, and in England the Ministry of Education and the Medical Officers of Schools Association have differing practices No wonder the W H O report concludes that any country wishing to introduce new regulations will get no real guidance from a study of existing conditions Nevertheless there is without doubt a firm trend towards surveillance rather than exclusion, and the child who is known to be naturally immune or to have been immunised is usually allowed to go to school Perhaps the most pleasing feature is that in several countries rubella is recognised as disease for girls to have before they are likely to become pregnant

France, justly proud of the part played by Ramon in perfecting diphtheria immunisation, excludes from scho children who have had the disease for 30 days after clinical cure or until 8 days after two negative culture Contacts if immunised are allowed to go to school, but not they are excluded for 15 days Carriers ar[illegible]cluded until a medical certificate is produced The ma[illegible] of diphtheria in France is a good example of how advantage of recent advances, and this policy encourage active immunisation

It is surprising to find that there is virtually n formity whatever in the measures prescribed for s to deal with diseases whose epidemiology, evolutio method of spread are well known The only positive that emerges from this study, when compared wit

onclusions drawn from corresponding work in 1952, is at there is a tendency to reduce the stringency of clusion measures for both patients and contacts

DEFORMITIES OF LONG BONES

children severe deformities of the long bones iated with generalised skeletal disturbance tend to ogressive, and to recur under the strain of weight- ig or even of muscle action Sofield and Millar[1] long used a method of fragmentation and realign- of the deformed long bones

i deformity of the femur the operation involves sub- al exposure of the entire shaft with osteotomy through ximal and distal metaphyses The isolated shaft is into 2, 3, or 4 pieces, which are removed and threaded most appropriate order along an intramedullary rod isses into the intact ends of the bones Reconstitution mur is rapid, but growth of the epiphyses away from eaves a new part of the shaft which may bend or t its junction with the intramedullary pin A longer have to be introduced, the end of the bone being upon the rod

method has also been used *in the* treatment of al pseudarthrosis of the tibia, although here its are not so great In view of the stimulation of by fracture of the long bone, Sofield and Millar tended their fragmentation procedure to the treat- men f the short leg But, as with other methods which rely on the stimulation of growth by periosteal raising or y fracture, the gain in growth seems to be slight and onstant

PREAD OF STAPHYLOCOCCI FROM HOSPITAL TO COMMUNITY

HE danger to the public when "hospital" staphy- cci are taken home by patients is not always appre- d, even by doctors Many workers have shown that es occur—that the community is being infected by , usually highly virulent, which are selected by of their resistance to the common antibiotics[2-8] rth et al[9] describe an investigation in which 1287 were seen at home between one and five months th There was staphylococcal disease in 45% of families in which the babies had been infected y left hospital, but in only 9 5% of the families babies had been clinically free from infection left the hospital carrying the epidemic strain, five months later three-quarters of the mothers nd of the other members of the family were o be carrying the same strain, while 8 mothers, 3 thers, and 8 siblings had developed actual staphylococcal sions

Boils and abscesses can cause a great deal of pain and iconvenience, but there are two groups of people for hom contact with a "hospital" staphylococcus may be iore serious The first are children under 2 years of age, who are particularly susceptible to staphylococcal pneumonia this is described by Morris[10] as now one of the commonest serious diseases in pædiatric practice, whereas formerly it was rare It is difficult to diagnose and rapid and severe in its course Isbister[11] has reported 22 cases, of which 6 were fatal, 17 could be traced to hospital infection—2 occurred in toddlers whose mothers had just returned from maternity hospitals with a new baby (and a staphylococcus) The second type of patient who is in particular danger from the hospital-derived staphylococcus is the one with influenza Goslings et al[12] in Leiden sought a history of staphylococcal *infection in the families* of 40 patients whose influenza was complicated by staphylococcal pneumonia In a third of this group identical organisms were isolated from the sputum and from skin lesions, which were found more often in family contacts than in the patients themselves

Obviously, the most important way to prevent this spread of virulent staphylococci to the community is to clear the organisms from our hospitals—particularly the maternity units The search for methods of doing this continues[13-16] One method which seems to be of particular value is the application of hexachlorophane, as an emulsion[16] or a powder,[17] to areas of babies' skin where staphylococci grow most prolifically

Another way of approaching the problem is to make certain staphylococcal infections notifiable We have not the same problem here as in America, *where mother and* baby leave hospital four or five days after delivery, and where the majority of hospital-acquired infections *become manifest at home* Thus, in the U S A the original outbreak may be missed,[14] and only appreciated afterwards because of the large number of readmissions But we must look out for the more severe infections, such as breast abscess, empyema, pneumonia, and osteomyelitis, which take several weeks to develop At the moment there is no way of establishing the incidence of these or of tracing them back to the hospital of origin A British Medical Association committee[18] reporting on possible changes in notifiable diseases recognised this defect by proposing compulsory notification of any coccal disease of a child or mother within twenty-one days of delivery In New South Wales the notification of staphylococcal mastitis, pneumonia, and infections of infants under 4 weeks old is now compulsory There are certain difficulties about this[11]—difficulties, for example, of definition and of diagnosis Isbister[11] considers that the time limit of four weeks is too short, as she has found that most of the really dangerous complications develop after the neonatal period Some form of notification is essential, if only to make us aware of the extent of the problem

At this season it is especially important to appreciate the danger to an influenzal patient if there is a staphylococcal infection in the family The antibiotic-resistance pattern of the organism should be discovered as soon as possible, *and penicillin and the tetracyclines should* be withheld unless the staphylococcus is known to be sensitive to them Most "hospital" strains are not

REMUNERATION OF DOCTORS AND DENTISTS

Royal Commission's Report

THE Royal Commission on Doctors' and Dentists' Remuneration was appointed in 1957 with Sir Harry Pilkington as chairman Its report, signed by all but one of its members, has been issued this week [1] The commission finds that the present remuneration of doctors is inadequate, and it proposes the establishment of machinery to keep remuneration under review

The commission was appointed to consider

1 How the levels of professional remuneration from all sources now received by doctors and dentists taking any part in the National Health Service compare with the remuneration received by members of other professions by other members of the medical and dental professions, and by people engaged in connected occupations,

2. What, in the light of the foregoing, should be the proper current levels of remuneration of such doctors and dentists by the National Health Service,

3 Whether, and if so what, arrangements should be made to keep that remuneration under review,

and to make recommendations

GENERAL OBSERVATIONS

The report opens with five important general observations ·

1 There has been no accurate knowledge of the level and spread of earnings in the medical and dental professions nor of how their earnings compared with those of other people of broadly similar attainments

2. There has been no attempt to ensure that the recommendations of the Spens Committee accepted by the medical profession and the Government as to the spread of earnings among general medical practitioners were carried out.

3 There has been a complete absence of any effective machinery to see that dentists earned what had been intended, as a result they have earned more

4. Owing to the shortage of dentists, general dental practitioners have worked longer hours and have earned more than was envisaged by the Spens Committee, and more than general medical practitioners

5 The uniformity of pay scales in the hospital service has not taken account of the wide variation in attractiveness to the young doctors of the various types of hospital

The commission declares "We reject the suggestion that doctors' and dentists' pay can be settled by the application of a formula, tied to the cost of living, or to a special index", and it recommends the setting up of a review body, somewhat similar to the Advisory Committee on the Higher Civil Service, to watch the levels and spread of medical and dental remuneration, and to make recommendations to the Prime Minister

> "The main task of this Body will be the exercise of the faculty of good judgment, and it must be composed of individuals whose standing and reputation will command the confidence of the professions, the Government, and the public. It must be regarded as a better judge than either the Government or the representatives of the professions as to what the levels and spread of medical and dental remuneration should be
>
> "While the Government cannot abrogate its functions and responsibility for ultimate decisions we are insistent that the recommendations of the Review Body must only very rarely and for most obviously compelling reasons be rejected"

The commission attaches great importance to prompt action by the Government in dealing with the review body's recommendations "Nothing will restore confidence between the professions and the Government more than experience of really prompt action on the recommendations of the Review Body"

The commission declares that, now that the vast majority of their earnings come from the State—"a monopoly employer for practical purposes"—doctors and dentists should have their remuneration settled by external comparison, principally, though not necessarily exclusively, with professional men and others with a university background in other walks of life.

In deciding where doctors and dentists should stand in relation to members of other professions, regard should be paid among other matters to the general trend of recruitment in quality and quantity, and to the relative status of the medical and dental professions and of other occupations in other countries But earnings should not be determined by short-term supply and demand In common with the Willink Committee, the commission does not propose that attempts be made to alter the level of recruitment by adjusting remuneration

The report suggests that to supply the review body with the necessary information, the Government must procure a continuous flow of classified statistics showing the level and spread of earnings among doctors and dentists and all who may be regarded as comparable, and this information can most simply and reliably be obtained from the Inland Revenue, with safeguards against identification of individuals or small groups

As regards dentists the commission views "with disfavour the failure of the profession and of the Government to establish a method that would ensure that dental earnings match intentions

> "Since earnings continue to rise we recommend that no changes in current payments for items of dental service should take place until effective machinery is working to ensure that intentions as to levels of earnings are fulfilled.
>
> "We accordingly recommend that a permanent study group should assess and keep under review rates for items of service based on proved performance of dentists It will be for the Review Body to say what dentists in the future ought to earn, it will be for the study group to arrange that this is what they do earn"

Doctors and dentists in the public service, the report continues, should not be used as a regulator of the national economy Their earnings should not be prevented from rising because of a fear that others might follow

> "This does not mean that we consider that either doctors or dentists should ever have a fixed place in a changing world. Over the years, in this country and in others, the financial position held by doctors or dentists may rise in relation to some and fall in relation to others, and in relation to each other, for various reasons including the maintenance of a proper balance of recruitment between these and other professions"

Routine matters of pay adjustments and of general conditions of service should be settled by existing methods of negotiation, whether direct or by a Whitley committee.

The commission gave special consideration to doctors in their preregistration year and first few years of registered practice

> "Today many young science graduates start earning salaries in the early twenties and in many professions earnings are quite substantial well before age thirty In the light of this, the total earnings of doctors up to age thirty are too low, and we are recommending substantial increases for junior hospital appointments and for trainee assistants, we expect these to

affect the salaries paid by general medical practitioners to their assistants "

EVIDENCE ABOUT REMUNERATION

The commission quickly realised that to obtain information about earnings in the medical, dental, and other professions it would " have to embark upon a good deal of original research ", and this it painstakingly did

It has eliminated from all its statistics doctors, dentists, and others (except university teachers) not working full-time The commission concentrated on those aged 30–65, but it remarks that the figures should be interpreted cautiously, as they are affected by the age structures of the samples Furthermore, the figures of income returned by general medical and dental practitioners and by fee-earners in other professions included depreciation allowances on capital outlays (In the case of general medical practitioners these were shown by an expenses inquiry to have averaged £128 in 1955–56, while in the case of general dental practitioners the commission's survey disclosed a figure of £102) Again, the earnings of general practitioners represent the amounts actually received by them in 1955–56, and take no account of arrears

In 1955–56 median earnings in all ages (including those under 30 and over 65), and in those aged 30–65, and estimated total earnings at ages 30–65 were as follows

	Median earnings *All ages* *	*Median earnings* *Aged 30–65 yr* *	*Total earnings 30–65 yr* †
Medical ‡

Graduates in industry	*1260*	*1570*	84,000

* No deductions have been made to allow for depreciation, nor, in the case of general medical practitioners, have any additions been made to allow for uneven distribution of pool balances

† These figures are arrived at by taking the average earnings of each age-group, multiplying them by the number of years in the group (five or ten), and adding them all together This device greatly diminishes the influence of temporary differences in age distribution, and takes account of the fact that some professions are most remunerative at one age and some at another The career earnings may be said roughly to represent what a man in each profession who was 30 in 1955 might then reasonably have expected to earn if he worked on a full-time basis until age 65, provided all the circumstances of 1955 remained unchanged

‡ Men only

ASSESSMENT OF EVIDENCE

THE commission remarks that the relationship between earnings in different professions is determined not only by considerations of precise justice and logic, but also by tradition and economic pressures of various kinds Moreover, since increases in professional remuneration are often made at long intervals, in some professions a substantial change may have taken place shortly after the period in which its remuneration was studied Nevertheless, a broad picture can be seen

The Willink Committee, reporting in 1957, suggested that " the reduction of the student intake by about a tenth from as early a date as is practicable would meet the case " The commission found that, whether or not as a direct result of the committee's recommendations, the intake of medical students fell from 2564 in 1957–58 to 2504 in the following year " We are informed that at present all the medical training places can be filled with suitable candidates, but there is no longer the flood of applications that was characteristic of the immediate post-war period The broad conclusions seem to be that the supply of candidates for training as doctors is reasonably close to requirements, and the question of using remuneration as an instrument either for encouraging a greater flow of potential doctors, or reducing the present flow, does not arise "

As regards dentists, since all available places in the schools are now well occupied, it would be pointless to use remuneration as a means of obtaining more potential dentists On the other hand " The level and quality of recruitment to the medical and dental professions may be affected by our recommendations, or the information we publish about the earnings in other professions Any such changes in the level or quality of recruitment would be matters for consideration when medical or dental remuneration is reviewed in future "

The professions, says the report, in giving evidence to the commission laid great emphasis on what was sometimes called " proper implementation of the Spens Reports "

> " We have studied all three reports with great care, but while fully acknowledging the valuable work done by the Committees in providing a basis on which the remuneration of doctors and dentists could at that time be established, we state emphatically that the remuneration of two great professions in the National Health Service can no longer be governed by their recommendations "

The commission acknowledges that its recommendations may lead to repercussions in other fields,

> " and that other groups, some paid from public funds, may argue that implementation of our recommendations for doctors and dentists in the National Health Service ought to be accompanied or followed by increases in their own remuneration it would be quite wrong for us to revise our recommendations for fear of the cost of possible repercussions "

The commission adds that if, after new levels of remuneration are introduced for doctors and dentists in the N H S, any other doctors and dentists obtain consequential increases in their remuneration, it would also be quite wrong to use these as arguments for further increasing the remuneration of the N H S doctors and dentists

The commission reached five main conclusions

1 At the time of its appointment current earnings of doctors and of dentists were too low

2 Since 1957 earnings in other professions and in industry and commerce at levels comparable with those of doctors and dentists have increased, by rather less than those of general dental practitioners, but by rather more than those of doctors generally and of dentists in the hospital service

3 The commission should recommend levels of remuneration to apply from Jan 1, 1960 Since, however, it was asked to recommend current earnings in 1957 at the time of its appointment, there should be some payment to general medical (but not dental) practitioners and to doctors and dentists in the hospital service to cover the intervening period There should be no retrospective payment for any period prior to the commission's appointment

4 Within the medical profession the overall relationship in earnings between the two branches—the hospital service and general practice—should be broadly maintained unchanged

5 The young doctor under 30 years of age has been underpaid to a relatively greater extent than older doctors, but the young dentist *has not* been underpaid in relation to the older dentist

" After careful consideration of all the factors we have decided that in 1957 average earnings of both doctors and dentists for the whole career period between ages 30 and 65 should have been about £7000 more than they actually were in 1955-56, and that by 1st January 1960 they should have increased by a further 12 per cent. This would give average 'career earnings' from January 1960 of about £102,000 for the National Health Service doctor and of about £96,000 for general dental practitioners. We have also decided that as from 1st January 1960 the younger doctors should receive rather higher percentage increases."

HOSPITAL AND SPECIALIST SERVICES

The suggested new scales of salaries are set out in the accompanying table.

Consultants

The commission recommends that as from Jan. 1, 1960, the scale for whole-time consultants should be £2550 at age 34 or on appointment later × £150 (8)–£3750, then after a second year at £3750 one further increment of £150–£3900. The commission has lengthened the scale slightly in order that consultants can look forward to increasing remuneration for a rather longer period than in the past.

The commission is not persuaded by the arguments in favour of weighting, but it admits that its immediate abolition would alter the relativities between whole-time and part-time consultants more than seems justified at present. It therefore recommends retention of a limited amount of weighting on the remuneration of part-time consultants in post on Dec. 31, 1959, and on that of certain others.

No change is recommended in the circumstances in which payment is made for domiciliary visits.

Of distinction awards the commission says:

"For our part, we agree that some considerable differentiation of income among consultants is necessary in order that good work may be encouraged and rewarded and that there may be a spread of income among consultants comparable to that in other professions. Two common methods of securing differentiation in other fields are not open to the consultant so far as his Health Service work is concerned. Unlike some professional men in private practice he cannot vary his fees in accordance with his professional standing, and unlike the salaried employee in most fields he cannot look forward to promotion. In these circumstances we consider the awards system is a practical and imaginative way of securing a reasonable differentiation of income and providing relatively high

PAST, CURRENT, AND RECOMMENDED SCALES

Grade (1)	Scales payable when Royal Commission was appointed. (2)	Current scales (i.e., column (2) plus two interim increases) (3)	Scales proposed by British Medical Association in 1957 figures (4)	Recommended scales as from Jan. 1, 1960 (5)
Consultants (a) Basic scale	£1800 at age 30 or less. £1950 at age 31 £2100 at age 32 or over × £125 (8)–£3100	£1965 12s at age 30 or less £2129 8s at age 31 £2293 4s at age 32 or over × £136 10s (8)–£3385 4s	At age 32 the scale to be £2700 × £162 10s (8)–£4000 *	£2550 at age 34 or on appointment later × £150 (8)–£3750, then after a second year at £3750 one further increment of £150–£3900
(b) Distinction awards	A awards—£2500 (to 4% of all consultants) B awards—£1500 (to 10% of all consultants) C awards—£500 (to 20% of all consultants) (The basic scale of consultants with A and B awards is abated by £300 and £200 respectively.)	As in column (2)	A awards—£4000 (to 4% of all consultants) B awards—£2400 (to 10% of all consultants) C awards £800 (to 20% of all consultants)	100 A Plus awards of £4000 300 A awards of £3000 800 B awards of £1750 1600 C awards of £750
Senior hospital medical and dental officers	£1475 at age 30 or less £1525 at age 31 £1575 at age 32 or over × £50 (9)–£2025	£1610 14s at age 30 or less £1665 6s at age 31 £1719 18s at age 32 or over × £54 12s (9)–£2211 6s	At age 32 the scale to be £2160 × £130 (8)–£3200	£2000 at age 34 or on appointment later × £75 (4)–£2300, thereafter increments of £100 every second year–£2700
Senior registrars	£1100 in the first year £1200 in the second year £1300 in the third year £1400 in the fourth and any subsequent years	£1258 8s in the first year £1372 16s in the second year £1487 4s in the third year £1601 12s in the fourth and any subsequent years	£1620 in the first year £1800 in the second year £1980 in the third year £2160 in the fourth year Further increments of £180 per annum to be given for any further years in the grade while awaiting consultant posts.	£1500 in the first year £1600 in the second year £1700 in the third year £1800 in the fourth year £1900 in the fifth year £1900 in the sixth year £2000 in the seventh year £2000 in the eighth year £2100 in the ninth and any subsequent years
Registrars	£850 in the first year £965 in the second and any subsequent years	£972 8s in the first year £1103 19s in the second and any subsequent years	£1260 in the first year £1440 in the second year Further annual increments of £180 for each additional year in the grade.	£1250 in the first year £1400 in the second and any subsequent years
Junior hospital medical officers	£775 × £50 (6)–£1075	£886 12s × £57 4s (6)–£1229 16s	£1100 × £100 (5)–£1600	£1100 × £60 (8)–£1580
Senior house-officers	£745	£852 6s	£1080	£1050 on appointment at age 27 or under £1100 on appointment at age 28 or over
House-officers	£425 per annum for first pre-registration post held £475 per annum for second and any subsequent pre-registration post held £525 per annum for any post held when fully registered	£486 4s per annum for first pre-registration post held. £543 8s per annum for second and any subsequent pre-registration post held £600 12s per annum for any post held when fully registered.	Preregistered £555 per annum. Fully registered £635 for first post held. £715 for second post held.	£675 per annum for first post held. £750 per annum for second post held £825 per annum for third and subsequent posts

*The British Medical Association also proposed: Weighting for part-time service should be re-established at pre-1954 levels. Consultants appointed after age 32 should be placed on the scale according to age and experience. Domiciliary consultation fees should be increased by 60%. The obligation on the whole-time consultant to perform eight consultations per quarter without fee should be abolished.

earnings for the 'significant minority' to which the Spens Committee referred We therefore unreservedly support the continuation of the system "

It adds that at some time in the future selection for C awards might be made regionally

The commission finds nothing surprising in the different proportions of consultants in different specialties who hold distinction awards "Some specialties require more extensive training and experience and involve more difficult techniques and a heavier responsibility than others" On the other hand the commission is not satisfied that the number of awards should always be decided on the basis of percentages of all consultants, and it recommends that for the years 1960–62 awards (on a whole-time basis) be made as follows 100 A-plus awards of £4000, 300 A awards of £3000, 800 B awards of £1750, and 1600 C awards of £750

Senior Hospital Medical Officers

These, says the report have reached the maximum too soon, and this maximum has been too low in relation to other grades The commission recommends as from Jan 1, 1960, the following scale £2000 at age 34 or on appointment later ×£75 (4)–£2300, thereafter increments of £100 every second year–£2700

House-officers

"We consider," says the commission, "that house officers have been greatly underpaid both in relation to their seniors and in relation to what is paid to comparable people in other professions" It recommends a salary of £675 per annum in the first post, of £750 in the second post, and £825 in the third and subsequent posts

Senior Administrative Medical Officers

The maximum of the scale of remuneration paid to senior administrative medical officers in the largest regions should, as until recently, be the same as that of a full-time consultant, with a C award, and the whole scale should consequently be recast

GENERAL PRACTICE

The Pool

In the commission's view, the pool system of remuneration, though unusual, has a number of practical advantages, and recommends a continuance of the system, but not in precisely its present form

"It has been suggested to us by Government witnesses that the pool should be calculated by reference to the number of users of the service rather than of the doctors providing it The main objection to such a change is that it would not be possible, as it is under the present system, to decide upon a level of earnings for the average doctor and be sure of achieving it If the pool were based on the number of patients and not on the number of doctors there would be a tendency, in current conditions, for remuneration to fall, since the population is not increasing as fast as the number of doctors In order to restore the intended level of earnings it would then be necessary to make successive increases in the rate of capitation and other fees No worthwhile public economies would be likely, but doctors' incomes would fluctuate more, which is not a desirable feature in a system of remuneration We therefore recommend that no change be made in this matter, and that the pool continue to be calculated by reference to the number of doctors"

"On the other hand we consider that the balance of advantage lies in the removal from the annual pool calculations of private earnings (from private patients, examinations for insurance companies, part-time industrial practice, and other private sources) Private earnings are very difficult to ascertain on an exact or agreed basis, and it is for this reason that we recommend that the present unsubstantiated figure of £2 million be dropped from the annual pool calculations, and that no attempt be made in future to calculate and allow for annual fluctuations unless there is reason to believe that the alteration has been substantial"

Exchequer contribution to superannuation should no longer be deducted in arriving at the sum payable to doctors The reasons for its inclusion hitherto in the pool have now lost their force

Special inducement payments made to practitioners in certain sparsely populated areas should be taken into account as income from the National Health Service in making up and distributing the pool

The pool should be based on a predetermined average net income from all official sources (excluding the differential payments referred to below), this should be multiplied by the number of unrestricted doctors under 70 in the service, there should be added an annually estimated total figure of practice expenses and subtracted an annually ascertained figure of earnings from hospitals, local authorities and official sources outside the National Health Service

Recommended Levels and Distribution

As from Jan 1, 1960 there should be paid into the pool the sum of £2425 per annum in respect of every practitioner below the age of 70 providing unrestricted general medical services No change is recommended in the general system of allowing for practice expenses

No detailed scheme is suggested for the distribution of the pool, but the report adds the following comments

"First, while we entirely approve of the efforts that have been made, and successfully made, to encourage the formation of partnerships, we feel that the financial incentive at present provided is somewhat excessive Secondly, while we fully approve the policy of giving to the rural practitioner some financial recompense for the facts that he cannot, in a scattered practice, attend so many patients as he could if they lived closer together, and that his expenses in attending them will be proportionately greater, our figures reveal that here again, in England and Wales at any rate, a sound measure has been overdone We accordingly hope that in the scheme of distribution to be worked out the special benefits at present given at the expense of other practitioners to partners and to rural and semi-urban practitioners, while not abandoned, may be relatively somewhat reduced Thirdly, in order to mitigate to some extent the preponderant influence of list size as a determinant of earnings, we hope that, where practicable, greater weight will be given in the scheme of distribution to items other than capitation Fourthly, we trust that the system of initial practice allowances, subject to any appropriate adjustments in amount, will continue to be operated for the elimination of underdoctored areas

"Finally, we regard it as important that the distribution of the pool balance should be made more promptly, and that the amount left to be distributed in this way should be greatly diminished"

It had been suggested that the financial recommendations should be linked to a proposal to reduce the maximum permitted list of patients, but the commission are convinced that this is not a question they are competent to settle, and indeed, such is the variation in human capacity and local circumstance, that they doubt whether anyone is competent to set a fixed and universal limit to the number of patients a doctor should have The absolute maximum must clearly be above the number that it is thought an average practitioner can handle in average circumstances If the maximum should be reduced the revised scheme of distribution that will then have to be made should be so devised as to reduce as little as possible the already inadequate spread of incomes, and as not to cause a substantial reduction in the earnings of individual practitioners already established. In any revision of the regulations regarding list size, care should also be taken not to render it impossible for a practitioner who employs an assistant to find the money to pay him adequately.

General-practitioner Differential Payments Scheme

Over and above the finance needed to meet other recommendations, a special fund of £500,000 per annum should be provided expressly to recognise distinguished general practice by additional remuneration. While leaving the details of such a scheme to be worked out by the profession and the Government, the commission suggest the following:

(a) The additional remuneration of a selected general practitioner should be not less than £500 per annum and might well amount to £1000 or even more.

(b) Those selected for the additional remuneration should normally continue to enjoy it until retirement.

(c) The addition should be treated in all respects as part of the practitioner's National Health Service remuneration.

Assistants

Trainee assistants are paid (indirectly) by the State and it is recommended that for the sum of £775 that was prescribed in 1955–56 there should be substituted as from Jan. 1, 1960, the sum of £1150 with such adjustment of the car allowance as may be deemed fair. For other assistants the position is not so simple, since their payment and conditions of service are governed by individual contracts with their principals, and the report does not recommend a standard or indeed a minimum rate. "We trust, however, that the remuneration of assistants will in fact rise in keeping with that of all other young doctors."

Dissenting Report

Prof. JOHN JEWKES, in a memorandum of dissent, says:

" in my opinion, the recommendations of my colleagues in regard to the level of earnings of general practitioners and of part-time consultants will not suffice to restore confidence in these two vital sections of the profession, nor will they provide in the long run an adequate supply of doctors of quality to meet the needs of the service and any improvements that may be sought in it."

Professor Jewkes' recommendations include the following:

1. That the annual earnings of general medical practitioners in the N.H.S. should be based, as from Jan. 1, 1960, on an average net figure (excluding private earnings and the Exchequer superannuation contributions) of £2550, and not on a figure of £2425 as recommended in the report.

2. That no change should be made in the weighting applied to the earnings of part-time consultants or senior hospital medical officers.

3. That no change should be made in the system of distinction awards except that the value of each class of award should be increased by 30%.

4. That fees paid to consultants for domiciliary visits should be increased by 30%, and whole-time consultants should be paid for all such visits.

5. That no retrospective payments should be made to general medical practitioners or to hospital staff.

6. That the new machinery for reviewing remuneration should take the form of an advisory council with somewhat wider functions than those suggested in the report. The council should review remuneration every three years, or sooner if the price level has changed either way by more than 10% from the time of the last settlement.

In England Now

A Running Commentary by Peripatetic Correspondents

WE lament the passing of Charlie. Our part of Lambeth, with its decaying early Georgian dignity, boasts a shopping centre of course, but one which adheres pretty strictly to the Shop Hours Act of 19-whatever-it-was, and if one gets a bit delayed in the Tube not a loaf of bread nor book of verse can one buy. Flasks of wine, obviously, can be purchased at a number of off-licences until 8.30 P.M. and after. Which is why we lament the passing of Charlie. His little shop up our road had a timeless quality. Generations of feet had worn its single step, and though it was scarcely larger than a phone-box Charlie packed into it an infinite number of useful objects from socks via stewing steak to gob-stoppers. He invariably had some kind of remedy for a depleted larder, and his light shone forth until after 9 P.M. "Knock me up if the door's locked," he offered cheerily. "Can't have folk going hungry." At times of particular difficulty, such as a late return on Bank Holiday Monday when the diminutive shelves had long been stripped of comestibles, he has been known to slip back into his cosy little room at the rear and emerge with a lump cut off the end of his own loaf. "Here," he whispered, "have half of mine—tide you over till morning," and then refuse payment. His industry and keen business sense paid off, and as the boutique could not take more than two customers (and then only at some inconvenience and hazard to the precarious boxes of bullseyes) an unruly conclave was to be witnessed in the road from half-past a fine five o'clock as scruffy kids bearing a few pence jostled with returning artisans and hurried housewives to gain entrance to the sanctum.

Yes, we lament the passing of Charlie. Time, woodworm, and rot had taken their toll of Charlie's aged terrace, and the demands of a nearby school for more playgrounds persuaded our Council some 13 years ago to condemn the lot. Lightheartedly we thought we were secure in the Law's delays, but shortly before Christmas the bulldozers moved in. Still shone the light forth, however, and though Charlie no longer troubled to stock up, business was as usual as the dust blew around him and we expected him to go down with his little shop, standing as it were upon the bridge. It was not to be. Charlie went, but with a whimper, not a bang. We glanced over to the usual place, and suddenly saw only the faded cigarette advertisements and a padlocked door. Charlie had folded his tents and crept silently away—and very nicely judged, too, we gather, because the Council had set him up in a much larger establishment three miles away just in time for the Christmas rush. Well, may he prosper, but we shall not see him again. To us his ghost lingers over the spot where asphalt will be laid and where children will soon play marbles and suck bullseyes.

* * *

A professor we know is not very good at answering letters, so a month or two ago we sent him a Mallaig kipper in a plain envelope. Yesterday we made a quick inspection of the correspondence compost heap on his enormous desk. The kipper has not yet surfaced, though our olfactory organs noted that its presence is becoming perceptible. But this is clearly the wrong approach. We should have remembered Sherrington's teaching that the sense of smell—"rich in affective tone"—quickly adapts and loses interest after the first encounter.

Now we have hit on a better plan. A firm of paper-makers has obligingly prepared for us, by a secret process, some special notepaper guaranteed to ignite spontaneously after 4–6 weeks. We are awaiting the result of this experiment with interest and hope that *The Lancet*, having accepted this preliminary communication, will be prepared to publish our full report in due course.

We expect, at least, to earn the gratitude of the professor by clearing his desk of unopened advertisements for Totamicin.

* * *

Last month I sat the examination for the membership of the Institute of Advanced Practitioners (M I A P) It is conducted by retired Civil Servants from the Ministry of Health The practical tests vary according to the type of practice The urban practitioner, for instance, may be given a number of passport photos to compare with standard subjects in a given time and make the appropriate comment on the backs, the rural doctor on the other hand may be given a bundle of E C 10s to sort into packets of a hundred or a given number of old ointment jars to wash out in a specified time Two of the questions from my written paper were

(1) Write brief reasons for any two of the following—Med 2a, OSCI, FW 8, BM 4(Rev), DMO

(2) The Ministry decides that seamless fine-thread two-way-stretch thigh-length hose shall no longer be prescribable Discuss an alternative treatment for chilblains

In my viva I was asked to give the percentage of the shillings collected on prescriptions which I allocated to my wife's pension fund, to dictate a letter to the National Assistance Board for a grant towards extra coal for a patient's television viewing-room, and to name the last five Ministers of Health in the correct order

I passed, paid my first annual subscription of 18*s*, and can now display a neat red-tape bow on the chest-piece of my stethoscope and the Institute's badge on my car This depicts a graduate in tattered academic dress discreetly manacled to an executive council clerk whose neat suit is unmistakably Savile Row

* * *

As a peripatetic psychiatrist I recently visited an Ayurvedic mental health research department, supervised by a scholarly Brahmin who is a pandit of the Vedic texts His assistant demonstrated the patients under their care, and his sweeping therapeutic optimism disarmed my dubiety about the potions, and the glutinous pastes for external application to the head, which were his principal medicaments At least the principle of *primum non nocere* seemed to be observed, and in psychiatry that is something

The pandit himself obliged with a brief outline of Vedic teachings on abnormal psychology On being asked whether he had difficulty in communicating with his Western-trained colleagues, he explained that he was even now studying Dr Curran's introductory textbook With a beatific smile, he pointed to the heavens and said " God bless him for his simple lucid explanations!" I have never heard any textbook receive such a heartfelt recommendation

DEPRECIATION

Look—there's plenty to do when you're thirty
Though the shadows are gathering fast
You may think that we old 'uns have had it,
You may think that we live in the past,
But old age makes a fellow more willing
And he'll work, just as long as he'll last

Now the way to survive when you're thirty
Is to plan for it, right from the first
You must Live while you're young—but not *too* much—
To get rid of Youth's feverish thirst,
And then stock up your mind for retirement,
It's the thoughtless ones feel it the worst

You don't squander yourself, when you're thirty—
You must always make sure of your sleep
Lord! The way you see some of 'em living
It's enough for the angels to weep,
But with care you can keep up your walking—
In the parks, where the hills aren't too steep

It's important to plan, when you're thirty,
You must *spread* yourself over your week
And you mustn't pay too much attention
If you notice your vertebræ creak,
And if ever you're hustled by youngsters—
Just you turn a deaf ear to their cheek!

Lowestoft

Letters to the Editor

MEDICAL NEEDS OF INDIA

SIR,—I was glad to read your editorial of Jan 30 in which you draw attention to the vast problem of India's medical needs

As one whose professional career for 31 years has been spent almost entirely in North India, I should like to endorse much of what you say, and also to emphasise the need of help from outside India In this connection I think two statements in your article may give a wrong impression, and thus tend to discourage any who might feel disposed to offer to serve in India

" Though some of the missionary hospitals and schools were outstandingly good and these continue—for example, Vellore, which has plenty of candidates for its medical school—the Government does not look with favour on missionary effort " It is true that the Government of India does not encourage the initiation of entirely new ventures, but I know of no restrictions placed on existing medical missionary work, and no interference with the running of medical institutions While there may be the occasional unfriendly official, the policy of the Central Government seems rather to encourage mission hospitals, many of which receive financial assistance, recurring or otherwise

The following figures taken from the latest edition of *The Christian Handbook of India*, give some idea of the present strength of mission hospitals run by Protestant bodies

Total no of hospitals	238
This includes	
Those of over 50 beds	60
" " " 100 "	55
" " " 150 "	14
" " " 200 "	7
" " 350 ,	4

There are many smaller units, and all have comparatively large outpatient departments

In addition there are 11 tuberculosis sanatoria and 52 leprosy institutions

Many of the larger hospitals are training nurses and are recognised by the Government for this purpose The nurses take the examinations of the local provincial Government

There are numerous dispensaries and some hospitals at work in village districts—that " backward countryside " where, as you rightly point out, the need is greatest

I was once personally assured by a Government official of some importance that the type of work being done by these small medical mission units is what is needed, and is commendable in his opinion

Your second statement, that " even medical missionaries are being slowly eliminated as replacements fall due, fewer being allowed to enter than to leave," does not accord with the facts

In its policy relative to the entry of foreigners into India the Government has shown no discrimination against medical missionaries, and no difficulties are placed in the way of those returning to their mission posts from leave in Great Britain

The admission of non-Commonwealth persons is subject to certain restrictions, however, but these apply equally to all, whether medical or non-medical, missionary or otherwise

It is true that the total number of medical missionaries is smaller than some years back, but this is largely due to a lack of new volunteers Another cause is the deliberate policy of mission hospitals in appointing Indians to posts of responsibility wherever possible, but this is an entirely voluntary matter

The door of opportunity for medical service in India is still open, especially to those with a missionary vocation

SAFETY-HARNESSES IN CARS

SIR,—We have read with interest Mr Barrett's article of Feb. 6 on the early treatment of stove-in chest. We notice that he does not mention the importance of safety-harness in cars, which in our opinion would have been a major factor in the prevention of these injuries. Mr Barrett states that "death steps in unnecessarily." We agree most of these deaths could have been prevented.

The commonest cause of these accidents is the driver or passenger being thrown forwards on to the steering-wheel or dashboard. This forward movement, which often includes the seat, could be prevented by a well-designed pelvic or pelvic-shoulder harness which is bolted to the floor with a reinforced steel plate some distance behind the front seat. This harness must be fitted with nylon webbing capable of withstanding a strain of several thousand pounds.

In addition, we should like to point out that in a detailed analysis of road accidents, over 30% of passengers are thrown out of the car at the moment of impact because the doors of the car spring open. These injuries, too, would be prevented by adequate pelvic or pelvic-shoulder harness.

It is, however, important that such harnesses be constructed of strong material, well designed, and securely bolted to the floor. Cheap materials, shoddy buckles, and belts which are looped around the back of the seat are utterly useless.

London, W.8.

THE THORN IN THE FLESH

SIR,—Following Dr Buhr's article (Feb. 6), this case-report shows that a generalised allergic response may follow injury by the thorn of the blackthorn.

A housewife, aged 61, was admitted to Southmead Hospital on Sept. 24, 1959, with the history that, while blackberrying three days previously, she had scratched her arm on a blackthorn bush (she was emphatic that it was blackthorn rather than blackberry). A few hours later she developed an irritating rash at the site of the scratch, which spread within a few hours to involve the whole arm, and then the rest of her body; at the same time she became increasingly short of breath. She was previously in good health, and there was no personal or family history of allergic disease or asthma.

On admission she was dyspnœic at rest, with a respiratory-rate of 46, and slightly cyanosed. Her temperature was 100°F. Her whole body was covered in a vesicular rash, secondarily infected in places. Examination of her chest showed pronounced expiratory effort, supraclavicular recession, generalised bronchospasm, and occasional, scattered rales.

Investigations showed a white-cell count of 14,400 per c.mm. (8% eosinophils, absolute eosinophil count 1150). Chest X-ray was normal.

Her bronchospasm and urticaria settled only slowly with 'Franol' (ephedrine, phenobarbitone, and theophylline) and chlorpheniramine, and she was fit for convalescence only after 18 days' inpatient treatment.

I am grateful to Dr Francis Page for permission to publish details of this case, which was under his care.

Southmead Hospital,
Westbury-on-Trym, Bristol.

B. A. LATHAM.

SIR,—Dr Buhr's article was most interesting, for blackthorn injuries are by no means uncommon in agricultural districts and prompt me to record this case.

A schoolboy, aged 9, was seen in the casualty department of High Wycombe Hospital on June 20 last year. He had fallen, injuring his left elbow, and had tenderness at the lower end of the humerus, with a full range of movement. There was no skin wound and X-ray revealed no bony injury. He was treated with a collar-and-cuff sling, and by June 30 was completely symptom-free.

On Oct. 16 he returned complaining of a lump in the left arm. There was a small mobile mass over the postero-medial aspect of the left humerus which was apparently in the triceps muscle. This mass was tender and thought to be an encysted hæmatoma resulting from the injury in June. No immediate treatment was advised. By Nov. 13 the tumour was slightly larger and still tender and mobile. Excision was advised, and on Nov. 24, 1959, with a bloodless field, the lump was explored and proved to be a mass of fibrosis (approximately $\frac{3}{4} \times \frac{3}{4} \times \frac{1}{2}$ in.) in the triceps muscle. The specimen was cut open at the end of the operation and a $\frac{1}{4}$-in. tip of a blackthorn was revealed. The wound healed satisfactorily, and when last seen the patient had no disability.

Section of the specimen showed "fat necrosis and granulation tissue containing some brown pigment suggestive of old hæmorrhage and a number of areas of foreign-body reaction."

This case is interesting in that there was no skin wound and nothing to show the entry of a foreign body. It illustrates a profuse foreign-body reaction which was stimulated by blackthorn.

I am grateful to Mr G. J. Walley for permission to record and treat this case.

The General Hospital,
Burton-on-Trent.

P. C. CASHMORE.

TREATMENT OF INGUINAL HERNIAE

SIR,—I think Mr Moloney (Feb. 6) is undoubtedly right in stressing the extra care that is taken with recurrent herniæ. In considering this problem of herniorrhaphy it is pertinent to recall that most recurrences after indirect herniæ are indirect herniæ again, and although we may be certain we have removed the sac high enough at the first operation, when the recurrence appears well within the first twelve months we might well ask ourselves where has this new sac come from?

Consideration of this over the last three years has led me to look for, and often find, lax peritoneum on the medial side of the neck of the sac which can be drawn out by hooking the medial half of the neck over the first joint of the index finger. In this way the peritoneum can be rendered as tense on the medial side as it is naturally on the lateral side. In this way I find I am removing more sac than I had done previously.

The second problem in the initial repair of herniæ is the securing of absence of tension on the repair particularly in the lateral part of the posterior wall, and if the absence of tension is being secured by release of the ligament from the fascia lata, from below rather than from above (Tanner slide), then simple pressure upwards with the finger after the repair is completed at the site of the internal abdominal ring will determine whether or not the ligament is being pulled down by any residual attachment of the fascia lata to it laterally.

If the impression is that there is still tension from below then it is necessary to further release the fascia lata laterally from its attachment to the fibres of the external oblique at its lower border. Confirmation of absence of tension using this method of repair can be gained if the patient is made to cough during the anæsthetic at the end of the operation when free movement of the lower border of the external oblique upwards will be seen to occur if there is no pull from below.

This principle of absence of tension applies equally to any form of repair or reconstruction, including a nylon "darn." It particularly applies if the mobilised ligament is being sutured up to the conjoint tendon, after release from the fascia lata.

The Memorial Hospital,
Peterborough.

D. W. BRACEY.

HIGH PLASMA-IRON IN PORPHYRIA

SIR,—Dr Hathorn and Dr Lamont (Jan 30) refer to high values of plasma-iron found in cases of porphyria (? acute intermittent porphyria) in Africans, and ask if plasma-iron has been measured "in cases with other types of porphyria"

In my translation of Vannotti's book,[1] it is stated that in acute intermittent porphyria a fairly regular increase in serum-iron has been found,[2] values ranging from 120 to 220 μg per 100 ml, and also iron deposition in the organs In his recent survey, Goldberg[3] found that the hæmoglobin in 27 cases of this disease lay within normal limits

The extensive deposition of iron in the organs of the congenital porphyria patient, Petry, is well known from the classic investigation of Borst and Königsdörffer[4] Two forms of iron-containing deposit were observed, hæmosiderin and a form in which iron was associated with a brown, amorphous pigment Quantitative serum-iron analyses are not available

In a case of cutaneous porphyria with easily traumatised skin and formation of bullæ, Langhof and Mildschlag[5] reported very high serum-iron values

Whilst it is difficult to interpret these findings with certainty, it is clear that iron metabolism may show signs of abnormality in the various porphyria diseases The role of iron in normal porphyrin[6] and hæm[7] formation is being very actively investigated at the present time in several different laboratories

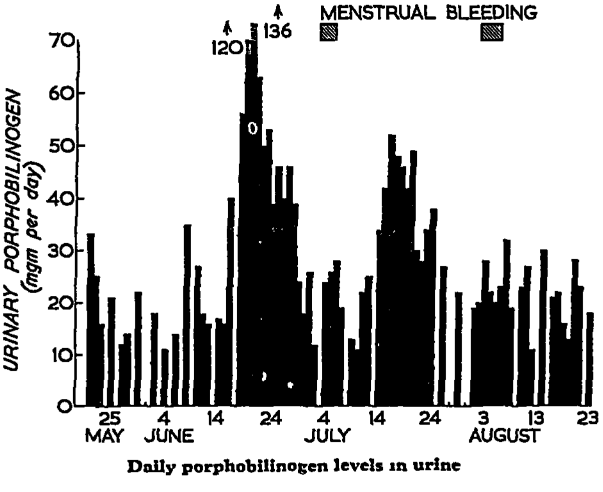
URINARY EXCRETION OF PORPHOBILINOGEN IN ACUTE PORPHYRIA

SIR,—It is well known that acute intermittent porphyria is more common in females than in males It is also known that in patients with acute porphyria attacks are provoked by endocrine imbalance Durst and Krembs[8] and Hughes[9] described instances of attacks during pregnancy and the puerperium Levit et al[10] recorded a case of acute porphyria with premenstrual attacks and exacerbations caused by progesterone injections More than a year ago we also observed two attacks in connection with endocrine dysfunction in a 46-year-old woman suffering from acute porphyria This presumably climacteric patient had had two periods of amenorrhœa, each lasting about six months and ending in menstrual bleedings and attacks of porphyria[11] With the determination of the daily output of the porphyrin precursor, porphobilinogen (P B G), in the urine, it was possible to demonstrate in this patient some relation between porphyrin metabolism and endocrine imbalance

We followed this patient for three months, beginning about nine months after her second attack, and we determined the daily P B G output in the urine by the method of Mauzerall et al[12] slightly modified The accompanying figure shows the daily P B G levels in the urine



Daily porphobilinogen levels in urine

In the first weeks of observation the patient had no menstrual bleedings (her last bleeding was in March, 1959) and no high urinary P B G levels either However, 14 to 16 days before her first (July 3–5, 1959) and second (Aug 2–5) bleeding there was an increase in the urinary P B G level Thus the period of high urinary P B G output coincided with ovulation During high urinary P B G excretion her clinical state deteriorated slightly, especially before her first bleeding

During our observation period a third bleeding has not been reported and she is again amenorrhœic Urinary P B G levels are not high

Our observations show that in this patient 14 to 16 days before bleeding after a period of amenorrhœa the P B G excretion in the urine increased This increase coincided with the time of ovulation The increased urinary P B G levels before the patient's first bleeding were similar to those observed during her attacks (140–165 mg per day) We suppose, therefore, that in this case endocrine imbalance plays an important role in precipitating attacks of porphyria

AUTOIMMUNE HÆMOLYTIC ANÆMIA WITH RENAL FAILURE DUE TO PHENACETIN AND P A S

SIR,—Your issue of Jan 2 contained an article on this subject by Dr MacGibbon and her colleagues Because of the rarity of such cases I should like to report another case[13] of a hæmolytic reaction due to *p*-aminosalicylic acid (P A S)

A 57-year-old man suffered from pulmonary tuberculosis for several years He had been treated with different antibiotics and with P A S Oral P A S was badly tolerated (vomiting, general malaise, and fever) It was therefore decided to give a P A S solution intravenously (15 g daily) with 250 mg of oxytetracycline His clinical condition improved, but at the beginning of the 10th infusion of P A S he had a violent reaction (lumbar pain, rigors, vomiting, and collapse), and the infusion was immediately stopped He became very anæmic, the hæmoglobin fell to 48%, the serum-bilirubin increased, and the red cells showed anisocytosis and spherocytosis After three days, when the patient was already recovering, we received the blood for serological investigations

Blood-group B₀, Rh-negative, direct Coombs test negative

Besides incomplete Rh antibodies anti-D, apparently the result of transfusions with Rh-positive blood, the serum contained a second antibody This antibody agglutinated the cells of the patient and other Rh-negative subjects, but only in the presence of P A S

[13] van Loghem, J J Jr 3rd International Congress of Clinical Pathology Brussels, July, 1957

No agglutination could be obtained when the other drugs which the patient had received (oxytetracycline, isoniazid, penicillin) were added to the patient's serum In the maximal concentration of P.A.S (500 mg per 100 ml) optimal reactions were obtained (titre 32) As the concentration of P.A.S diminished the titre fell gradually The antibody was still active after heating at 56°C for 20 minutes, but was destroyed by heating at 70 C for 10 minutes

Hæmolysis could not be demonstrated with fresh serum samples, nor with inactivated serum samples to which human or guineapig serum had been added as a source of complement The antibody in the patient's serum was not neutralised by the addition of P A S solution to the serum, nor could it be removed by adsorption on to packed cells, but it was completely removed after the addition of P.A.S — red cells

It seems well established that the antibody developed in the course of the treatment by intravenous injection of P.A.S , because repeated oral administration of P.A S was never followed by signs of abnormal cell destruction, and also because the antibody disappeared a few weeks after the intravenous P A S was stopped

Another case of autoimmune hæmolytic anæmia induced by P.A.S , this time by oral treatment, was recently observed by Dr J Dausset in Paris (unpublished observations)

SIZE DIFFERENCES AND SOCIAL CLASS

SIR,—In your editorial of Feb 6 on the Germ-free Animal you say that the difference in size between adolescent boys in social class I and those in social class V is no longer seen I believe this statement to be in error, as reference to the texts on growth [1] or to the original literature [2] will readily show On the contrary, the most striking thing about the changes in growth-rate which have occurred in the past fifty years is that *all* social classes are growing up earlier and that the difference between the classes, though it may have decreased a little, has not decreased as much as many of us would expect One is reminded of the parallel situation in infant mortality described recently by Professor Morris and his colleagues in your pages The reasons for the social class differences in growth-rate and in final adult size are evidently not simple, and the subject invites much more careful research

PRESERVATION OF MEDICAL RECORDS

SIR,—Your article (Feb 13, p 379) drawing attention to the British Records Association memorandum on the disposal of medical records is welcome The historian and archivist have a legitimate interest in medical records which should be as far as possible respected

Medical records are more than archives, however, and for half a century or so may help to preserve the lives and limbs of those to whom they refer, if they are intelligible and accessible The growth of procedures in modern medicine is reflected in increasingly complex medical records In this hospital the mean number of sheets recording a single admission was 9 3 in 1946, 12 6 in 1952, and 18 9 in 1956, although the mean duration of admission fell slightly during that time If the information thus recorded is to play its full part in exhibiting all features of an illness to those caring for the patient, either then or later, the record must be more than a sheaf of papers arranged at hazard.

The increasing bulk of medical records makes microfilming a likely solution to the problem of storage, microfilming is most effectively applied to a record system designed for it, precautions being taken to preserve documents in a physical state that permits microfilming without laborious preliminary treatment

With these two requirements of medical records in mind we have designed a system of clinical records which has been in operation at the United Cardiff Hospitals since April, 1958, it is proposed that microfilming of the new records will begin when they are 5 years old

POSTOPERATIVE DIARRHŒA

SIR,—A further point must be made concerning postoperative diarrhœa and Mr Schofield's letter of Jan 16 It is only in subacute intestinal obstruction, which may or may not occur postoperatively, that an intestinal hurry has been demonstrated using methylene-blue Two charcoal biscuits taken orally have also been employed to demonstrate this faster intestinal transit time The latter material does not diffuse and the same results occur

London, W 1

J J SHIPMAN

TOLBUTAMIDE IN THE TREATMENT OF ANGINA PECTORIS

SIR,—We were most interested to read the report of Professor Singh and Professor Bardhan (Dec 19) on progressive improvement in angina pectoris in 9 diabetics and 15 non-diabetics treated with tolbutamide Of interest to us, also, was their observation that the beneficial effect of the drug was not directly related to its hypoglycæmic effect

Early in our work with sulphonylureas we noticed that patients given tolbutamide experienced a feeling of general stability and wellbeing which was not related to the hypoglycæmic action of this compound, since it was observed even in those patients whose hyperglycæmia and glycosuria were not improved by such therapy It was also observed that shortly after institution of tolbutamide therapy some patients suffering from angina pectoris experienced an unanticipated relief from their painful attacks and were able to reduce or to eliminate entirely the use of nitroglycerin These studies were reported [1] in May, 1958 Subsequently, we noted that patients afflicted with intermittent claudication were also benefited by the use of tolbutamide, as shown by marked increase in claudication time or even complete disappearance of the pain on walking

In a paper which is now in press (*New York State Journal of Medicine*), we reported on a group of 41 patients with angina and/or claudication treated with tolbutamide for periods of twelve to forty-two months Among them were 18 suffering from angina pectoris, 20 with intermittent claudication, and 3 with both conditions 5 patients were given tolbutamide in conjunction with insulin, and the other 36 tolbutamide without insulin. Relief from pain was obtained in 16 patients with angina, in 15 with claudication, and in the 3 patients suffering from both conditions However, we should like to emphasise that in all our patients who were relieved from pain of angina and or claudication, the drug had no effect on the associated cardiovascular disorders Specifically, it did not lower the blood-pressure in 10 patients with hypertension, and failed to prevent myocardial infarction in 2 and diabetic gangrene which necessitated an above-the-knee amputation in 1 patient

Following the successful use of tolbutamide in diabetics with angina and intermittent claudication, we employed this drug in such conditions in 8 subjects with latent diabetes—that is, subjects with abnormally high glucose-tolerance curves but free from glycosuria and from clinical manifestations of diabetes, and in 10 non-diabetic persons Beneficial results were noted in both groups, but our series of such patients is not large enough for a definitive evaluation of the observed benefits

---

[1] Growth at Adolescence Oxford, 1955
[2] Social Implications of the 1947 Scottish Mental Survey London, 1953 Berry, W T C , Cowin, P J *Brit med J* 1954 i, 847, Hammond, W H *Brit J prev soc Med* 1957, 11 131

[1] *Metabolism*, 1958, 7, 213

The mechanism by which the sulphonylureas may produce relief from pain of angina and claudication has not been established yet Singh and Bardhan state that the benefit in their patients with angina may be accounted for by the reduction of blood-lactic-acid by the drug One possibility that we have considered in our patients relates to the influence that the drug may have on the metabolism of serotonin and that of adrenaline and noradrenaline Studies designed to clarify these points are now in progress in patients with angina and/or claudication, and will be reported in a separate communication

MAXIMILIAN FABRYKANT
BENJAMIN I ASHE

CHRISTMAS FACTOR IN THROMBOTEST

SIR,—Dr Nour-Eldin (Dec 12) repeats his claim that the thrombotest is not sensitive to Christmas factor I can only reply by giving the evidence on which I base my contention that it *is* sensitive

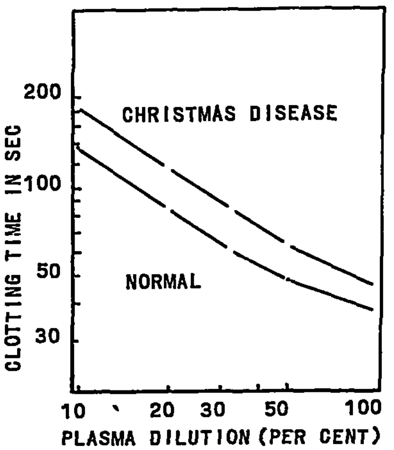
(1) Fig 4 in my paper (Nov 7) shows a dilution curve for plasma from a patient with Christmas disease This experiment was designed to imitate the effect of a disproportionate reduction of the Christmas factor during anticoagulant therapy The experiment shows that the thrombotest is sensitive to Christmas factor under these conditions

(2) The following figures give the results of thrombotest estimations in 10 patients with verified Christmas disease, all with characteristic joint bleedings

Case	*Christmas factor*	*Thrombotest*	*Case*	*Christmas factor*	*Thrombotest*
1	1 5%	63%	6	<1 0%	38%
2	1 0%	72%	7	<1 0%	48%
3	1 0%	44%	8	<1 0%	60%
4	<1 0%	72%	9	<1 0%	48%
5	<1 0%	65%	10	<1 0%	62%

Patients 1–5 were studied at the Institute for Thrombosis Research, the University Hospital of Oslo, and patients 6–10 by Dr Inga Marie Nilsson, the University Hospital (Almänna Sjukhuset) of Malmo, Sweden These studies show that the thrombotest gives abnormally low results in these patients However, I agree that the test is not sensitive to Christmas factor when the concentration of this factor is above 10% (see fig 4 in the original paper) Patients with mild Christmas disease may therefore have thrombotest values in the normal range

(3) In the accompanying figure the lower curve is the usual correlation curve of the thrombotest, obtained by diluting normal standard reference plasma The upper curve shows the result obtained when plasma from a patient with severe Christmas disease (Christmas factor less than 1%) is diluted in the same manner The difference between the two curves indicates the sensitivity to Christmas factor at different levels of the other clotting factors The two curves differ by about 50%—in other words, if the Christmas factor is reduced out of proportion to the other factors, the thrombotest value will be as much as 50% lower than it would otherwise be At a *level of 10–20%* of the other adsorbable factors, the clotting-times will increase rapidly when the Christmas factor is further reduced



Dilution curves for normal and Christmas-disease plasma The curves are drawn on double log paper

The thrombotest method is designed for the control of anticoagulant therapy The main point of interest is therefore the sensitivity to Christmas factor at a low level of the other adsorbable clotting factors The presented evidence indicates that the test rapidly detects a disproportionate reduction of the Christmas factor during anticoagulant therapy, since the thrombotest times will then increase For example, if a patient has a reduction of all four factors to 15%, and the Christmas factor then is further reduced, the thrombotest value will drop below the 10% level This, of course, is exactly the warning the clinician asks for

Thus, the sensitivity to Christmas factor is definite, but not as high as that of a specific test system This follows necessarily from the fact that the test is also sensitive to the extrinsic system Any test which is sensitive to both the extrinsic and intrinsic system must be less sensitive to deficiencies in only one of these systems than specific tests for each system However, this sensitivity is sufficient for controlling anticoagulant treatment The thrombotest method has never been recommended as a method for disclosing Christmas disease, nor for the quantitative determination of Christmas factor For this purpose methods must be used which reflect changes only of the intrinsic clotting system and not a combined test for the intrinsic and extrinsic systems such as the thrombotest

Oslo

P A OWREN

HIGH-PROTEIN DIETS

SIR,—In his letter of Dec 19 Dr Garrow says that I imply in my paper [1] that a retention of 50 g of nitrogen does not benefit the cachectic patient This retention was induced quickly, in 7 days, in surgical cancer patients and did not increase the albumin pool

As a worker in this field himself this finding should not have prompted such an interpretation from Dr Garrow An equilibrium between fixed tissue protein, as judged from body-weight or nitrogen excretion, and plasma-protein has been shown in dogs during both depletion by plasmapheresis [2] and repletion and maintenance by parenteral plasma injection [3] In each situation, however, a lag period occurred during which " reserve protein " was raided or restored It is certainly not incorrect to say that " lean muscle mass probably varies with the circulating protein mass," and Dr Garrow himself has recently shown a concomitant loss of plasma and tissue nitrogen in starved dogs [4]

The rapidity of turnover and low plasma-albumin observed in two patients with high gastrointestinal malignancy is surely contributed to by gastrointestinal protein leakage, as suggested by Dr Schwartz and Dr Jarnum (Dec 19) I prefer to believe both groups of workers are partially correct albumin is being " flushed " through the circulation to depleted tissues (Garrow) and being leaked into the gastrointestinal tract from the malignancy (Schwartz and Jarnum) This latter I have referred to as an internal protein shunt I should still hope to see direct correlative measurements between positive nitrogen balance and net gain in tissue-protein mass to substantiate the former

CATHETER DRAINAGE AND INFECTION IN ACUTE RETENTION OF URINE

SIR,—With interest I read the investigations of Mr Ashton Miller and his colleagues (Feb 6) in their endeavour to reduce the incidence of infection in patients admitted with acute retention

The method of sterilising the bottle, which I shall adopt, is excellent and simple, but I feel that the catheter-cum-connector-cum-rubber-tube falls far short of perfection Although the size of the catheter is not stated, those in common use encourage urethritis and ascending infection by virtue of their size and material The glass connector is often insecure or dismantled by meddlesome patients, or is pulled on by the heavy and insecurely anchored three feet of rubber tube

For the past year or more I have been using Gibbon's polyvinyl chloride 'Portex' catheter,[1] which, being five feet long, obviates any glass connections When passed with the usual aseptic and non-touch technique, urine immediately, by bladder pressure and capillary action, passes down the catheter before there is time to withdraw the obturator The non-irritating material lying loosely in the urethra minimises urethritis Air bubbles have little chance of ascending into the bladder, and subsequently the action of the small tube is syphonic.

Although I have not done routine cultures on all patients, it is gratifying to see how many arrive in the theatre with sterile urine, even after ten days

King's Lynn J O HARRISON

DANGER OF THE ABBREVIATION P.A.M

SIR,—In your leading article[2] on organophosphate poisoning, there were a number of references to the use of P A M (pyridine-2-aldoxime methiodide) in the treatment of this condition I drew attention[3] in 1958 to the danger which might arise in confusing this substance, under this abbreviation, with the much more widely used preparation of procaine penicillin with 2% aluminium monostearate also known as P A M, and the type of penicillin used for the treatment of yaws in mass-campaigns W H O Information Circular No 2 (January, 1959) on Toxicity of Pesticides to Man (p 8) also draws attention to the danger of confusing the two preparations, and it has been referred to elsewhere

TREATMENT OF TROPICAL EOSINOPHILIA

SIR,—The article by Dr Baker and his colleagues (Aug 22) was of particular interest to me, because our own work on similar lines was published in 1958[4]

151 patients in our series were divided in the following eight groups

(1) No treatment Minimum period of observation 1 month, 30 patients
(2) Diethylcarbamazine 13 mg per kg daily for 4 days, 13 patients
(3) Diethylcarbamazine 13 mg per kg daily for 8 days, 6 patients
(4) Diethylcarbamazine 6 mg per kg daily for 4 days, 16 patients
(5) Diethylcarbamazine 6 mg per kg daily for 8 days, 23 patients
(6) Diethylcarbamazine 3 mg per kg daily for 8 days, 17 patients
(7) Diethylcarbamazine 26 mg per kg for 1 day only, 19 patients
(8) Carbarsone 0 26 g twice daily for 10 days, 27 patients

Improvement after treatment was judged on the basis of amelioration of presenting symptoms and the degree of fall in initial total eosinophil-count

None of the patients in the control group kept without treatment had genuine relief Diethylcarbamazine was uniformly effective in lowering the total eosinophil-count and in producing symptomatic cure in the majority of patients Almost all the dosage schedules gave favourable results but minor variations were seen in the degree of effectiveness We observed that the administration of 6 mg per kg of diethylcarbamazine daily for 8 days produced the best results It is surprising to note how close is this dose to that of 5 mg per kg for 7 days recommended by Dr Baker

The results in the diethylcarbamazine groups did not differ significantly from those in the carbarsone group Relief of symptoms, however, was usually felt earlier with the diethylcarbamazine group

Dr Baker and his colleagues hint at the possibility of treatment with a single large dose of diethylcarbamazine We tried a single dose of 26 mg per kg and found that this schedule worked equally well

POLIOMYELITIS VACCINATION DOSAGE AND TECHNIQUE

SIR,—I was interested in a suggestion in your leading article of Jan 9 that the immunological response to the vaccine in the community may not be so effective as theoretical considerations would indicate I should like to raise a practical point, small perhaps, though not entirely unimportant, in the carrying out of immunisation programmes

Personal experience with the difficulties encountered in giving a full dose from a 1 ml vial in poliovaccination has led me to make inquiries into the literature and to have discussions with colleagues, from which it appears that it is of some importance that the full dose be given I blamed my ineptitude in getting the full dose out of the 1 ml vial, but I found that, even with great care, success was sometimes difficult I was interested to hear from others, who were expert, that they too had had difficulties

Several authorities (including Salk) are firmly of the opinion that the immunity response is proportional to the mass of antigen injected It would appear that the important type-1 component of poliovaccine does not always produce a satisfactory immunological response As with other antigens, individuals vary in the response to a given dose For these and for other reasons, it is important that the full dose should be given[1 2]

Independent investigation by the Salford City Analyst has shown that the amount of poliovaccine in the 1 ml vials was always above 1 1 ml (The lowest average in the series tested was 1 104 ml) In other words, there appears to be an "overage" in the vial—as is indeed the stated practice of the manufacturers in conformity with the recommendation of the *British Pharmacopœia*—so the manufacturers have played their part

Particularly when using the 1 ml vials, care is needed to see that the subject receives an adequate dose Losses, some of them almost inevitable under "field" conditions, and in busy surgeries and clinics, may be due to the following causes

The quantity of vaccine left in the nozzle of the syringe after use is surprising in amount, as can be proved by examination of the contents of the barrel after withdrawing the plunger after injection

There is also a quantity of vaccine left in the needle and holder

In addition there is loss due to inability to get all the vaccine down from the neck and head of the vial Perhaps with many volunteers waiting one should not expect that every doctor will spend a long time, which is sometimes necessary, in flicking the whole of the vaccine down

Some doctors use a special withdrawal needle to draw up the vaccine, here is another possibility of loss

There is hardly sufficient vaccine in the vial to cover losses when many bubbles have to be expressed

There may be loss from leakage after inoculation from the puncture in the skin

[2] *ibid* 1958, i, 1206

Experience has shown that under conditions of everyday practice, some volunteers have got less than 1 ml , occasionally far less than 1 ml

When it is remembered that different batches of vaccine are known to vary slightly in potency, it is to be hoped that the potency of the vaccine will be increased in future so that even with a smaller dose adequate immunity may still be obtained Until this is possible, it is wise for special care to be taken in technique in order to reduce avoidable losses in important and costly antigens

EFFECT OF MODIFIED EGG-YOLK FATS ON BLOOD-CHOLESTEROL LEVELS

SIR,—In a preliminary communication [1] we reported the modification of egg-yolk fats brought about by feeding sunflower-seed oil to hens A considerable increase (from 5 65% to 30 4%) in the di- and tri-unsaturated fatty acids was noted, and dietary trials of the " unsaturated " eggs in 2 subjects suggested that they might be consumed without raising cholesterol levels above the basal values achieved with a low-fat diet But Gordon et al [2] found no difference between the cholesterogenic effects of " normal " and " unsaturated " eggs, when ten yolks per day were fed

Additional dietary trials have now been carried out using both natural base diets low in fat (4% of calories) and the liquid-formula type of diets Our subjects were healthy medical students and interns who carried on with their normal activities during the test

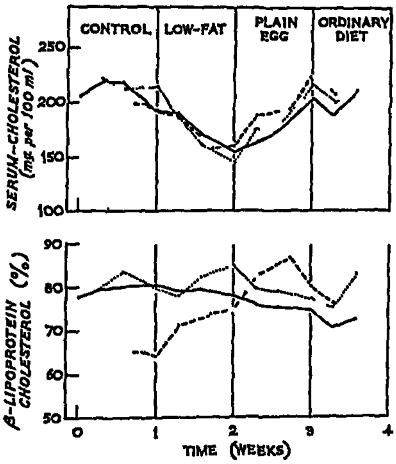

Fig 1—All 3 subjects showed a fall in serum-cholesterol during the low-fat phase Changing to the ordinary-egg formula resulted in a prompt rise of serum-cholesterol back to control levels in 2, and a slight overshoot in the 3rd

Natural food base (low-fat) diet—Two subjects received the basal low-fat diet for 2 weeks Ten " unsaturated" yolks were added per day for a further 2 weeks, the diet being held isocaloric by reduction of its carbohydrate content At the end of this period, the basal low-fat diet alone was continued for 10 days, and then ten ordinary yolks were added per day for a further 2 weeks Their response was as follows

Diet	*Duration*	*Serum cholesterol (mg per 100 ml)* *Subject 1*	*Subject 2*
Control	1 wk	241	156
Low-fat basal	2 wk	180	124
Basal plus 10 " unsaturated " yolks per day	2 wk	244	165
Low-fat basal	10 days	195	128
Basal plus 10 plain yolks per day	2 wk	250	179

Although no striking differences were seen between the " unsaturated " and ordinary eggs, the rapid rise in cholesterol levels which ensued when subject 1 received ordinary eggs (return to control values in 4 days) and the high final cholesterol levels in subject 2 might be significant Accordingly, a trial using formula diets was carried out

Formula diets—The formula base is that described by Beveridge et al [3] Egg yolks were added to supply 40% of the calories from fat This was equivalent to twenty-four yolks per day or approximately 6 6 g of cholesterol per day The results of two sets of trials using three different subjects in each group are shown in the accompanying figures

Despite a sixfold increase in the di- and tri-unsaturated fatty acids of the yolk, there was no significant difference in cholesterogenic effect, compared with ordinary yolks It should be pointed out that the feeding of sunflower-seed oil to hens does not reduce the cholesterol content of the yolk [4] Our subjects, therefore, received large amounts of cholesterol (2 75 g per day with ten yolks or 6 6 g per day on the formula diet) Egg yolks are known to have a very potent cholesterogenic effect Equivalent or even much greater amounts of crystalline cholesterol added to the diet have little or no effect on serum-cholesterol levels [5] The possibility therefore exists that this effect of egg yolks could be due to (1) a fatty-acid factor, (2) a phospholipid, or (3) lipoprotein-cholesterol factor

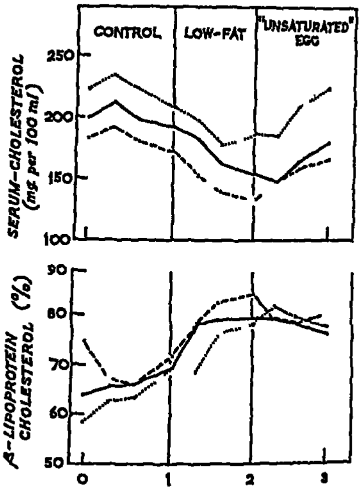

Fig 2—The "unsaturated '-egg formula resulted in a slower rise in serum-cholesterol which did not quite return to control levels in 2 subjects β-lipoprotein cholesterol rose during the low-fat phase and again on the egg-yolk diet

Although the unsaturated-fatty-acid content of our experimental eggs did not approach the optimum ratio postulated by Keys,[6] the changes were substantial enough to have shown some effect if this ratio were crucial It seems far more likely that the hypercholesterolæmia resulting from egg yolk is related to their phospholipid content Corwin,[7] Steiner and Domanski,[8] and Messinger et al [5] suggested that the high " lecithin " content of yolk might be responsible More recently Mustard [9] reported that liver extracts rich in phosphatidyl ethanolamine and containing 0 1% cholesterol produced hypercholesterolæmia and atheroma in rabbits Beveridge [10] reported that the addition of very small amounts of cholesterol to an " inactive " fraction of butter oils restored its cholesterogenic potency The possibility that some specific factor such as a phosphatide might act to enhance the effect of egg-yolk cholesterol would explain our results adequately Eggs are a rich source of phosphatidyl ethanolamine Reduction of the cholesterogenic effects of eggs might therefore be achieved by alteration of the phosphatide content or by a great reduction in the cholesterol content Experiments in this direction are now under way

SEVERE HYPERSENSITIVITY TO SULPHAMETHOXYPYRIDAZINE

SIR,—*Discussing this condition in their article of* Jan 23, Dr Maher-Loughnan and Dr Tullis say that "Side-reactions are slight and uncommon no serious sensitivity reaction had been reported" They make no reference to similar reactions that have already been reported, and readers may have gained the impression that side-reactions to sulphamethoxypyridazine are relatively rare

This is contrary to accumulating evidence, and I think it may be interesting to recall that in a series[1] of 85 patients taking the drug, reactions occurred in 13 In 1 patient it was a severe generalised bullous and ecchymotic eruption, much like that described by your contributors These and other cases indicate that sulphamethoxypyridazine causes side-reactions in more than 10% of cases, and severe bullous dermatitis seems to be an occasional feature

POLIOMYELITIS A DANGER FOR VISITORS TO NIGERIA

SIR,—From this hospital there has recently been flown to the United Kingdom a young European with poliomyelitis, on a respirator and attended by a medical and nursing team. Three weeks before, a team of doctors and nurses with a respirator had flown to the north of Nigeria to bring this young man into hospital here When he arrived he could move only the muscles of the eyes and lids During the three weeks it has been my privilege to watch the treatment of this young man, which I do not think could have been bettered in any other hospital that I know of When he left here this patient was able to use his facial muscles, could move fingers and toes, and could be independent of the respirator for about four minutes at a time This kind of case is met with not infrequently here, always in Europeans, sometimes the outcome has been less encouraging

Poliomyelitis is virtually unknown in the adult West African, although the late effects of "infantile paralysis" are seen from time to time in children It seems likely that the indigenous population becomes immunised in early childhood as a by-product of the primitive sanitary and overcrowded living conditions That such a state of affairs exists in North Africa is suggested by the studies of Paul and Horstmann[2] and in French West Africa by Said et al[3]

That is one side of the picture Another is that I have seen in the course of work in the medical outpatient clinic here a number of Europeans recently come to this country who have not been inoculated against poliomyelitis While travelling here, by sea, I made inquiries of fellow passengers, quite a number of whom were young adults coming to West Africa to teach or to escape the English winter by visiting relatives here It was a surprise to find that many had not been inoculated Lagos is only twelve hours by air from London and one reads almost daily in the local newspaper of visits of trade delegations and commercial representatives from Europe One wonders whether all these persons realise the risks they may be running

It is possible to get prophylactic inoculation against poliomyelitis in Nigeria but not, of course, as easily as in the United Kingdom The whole question of the inoculation of visitors and temporary residents is to be taken up here with the Federal Ministry of Health In the meantime it cannot be too strongly emphasised that prophylactic inoculation against poliomyelitis should be regarded as essential for any European coming to Nigeria even for the briefest of visits

Ibadan, Nigeria
HAROLD SCARBOROUGH
Temporary Honorary Consultant Physician

THE DIAGNOSIS OF BRUCELLOSIS

SIR,—Your note on my letter last week cannot be allowed to pass without comment for it contains several inaccuracies

You say that of my 35 proven cases 15 were diagnosed by agglutination tests, 2 by skin tests alone, and 18 by a fourfold rise in titre *after* the skin test (your italics) If you read again the table on pages 88 and 89 of the book *Brucellosis in England* you may see that 14 had an initial agglutination titre of 1 in 80 or higher, 2 of 1 in 40, and 4 more of 1 in 20 (Where you got the figure of 15 from I cannot understand) Next there were 14 cases where the skin test was positive 2 of these had already been confirmed by a high agglutination titre, but in 12 (not 2) of them the skin test confirmed the diagnosis That leaves 9 cases only in which the rising titre after the skin test was the sole laboratory evidence of the disease

You also say that you have seen no convincing evidence to justify my interpretation of this phenomenon May I refer you to the paper by Barrett and Rickards[1] which has now become a classic? They say

> "The results of this investigation would seem to indicate that intracutaneous injection of brucellin in non-sensitised persons does not provoke a significant antibody response, and that a rise in titre of brucella antibodies after brucellin indicates previous or current infection"

Then you depart into the upper regions of fantasy by saying that some of my cases may be psychosomatic and some P U O s Words fail me! It is just because difficult cases have in the past been condemned to such so-called diagnoses that I am fighting this battle P U O (pyrexia of undetermined origin) is not a diagnosis, though many patients present with it Granted that some of my patients had obscure pyrexia and also proof that they had at some time been infected with brucella surely it is reasonable to assume that there is some connection between the two I hold that it is a reasonable assumption and that in such cases the therapeutic test on which you pour such scorn might well be justified. Now for psychosomatic ailments This diagnosis is popular just now especially in the higher realms of academic medicine, but it is not really a diagnosis, merely a label which explains little We all know that the psyche may affect the soma and vice versa, and never more so than in brucellosis Robinson and Evans[2] say

> "A common feature of chronic brucellosis is the lack of abnormalities to be found in physical examination When the mild symptoms described occur in a patient with no apparent physical abnormality, the picture represents that classified as psychoneurosis"

Harris[3] says

> "The patient with the chronic illness, even though febrile and with demonstrable pathology and positive cultural findings, often presents the picture of radiant health The expression 'You feel so sick but you look so well' is frequently used by family, friends, and physicians, with the implication that the patient is a psychoneurotic if not a malingerer"

And Harris and Kemple[4] conclude

> "The demonstration of psychoneurosis or psychosis is not a sufficient basis for the dismissal of a diagnosis of brucellosis, nor is the converse true They are not mutually exclusive, indeed there may be a definite interrelationship"

I do not feel you are justified in saying "Many physicians will be unconvinced by the diagnosis in at least half the patients." If you had said "Many *pathologists* . . ." I would not quarrel with you. In common with most students of this disease I have been trying to press the point made so well by Barrett and Rickards:

[3] Harris, H J Brucellosis (Undulant Fever) New York, 1950
[4] Harris, H J, Kemple, C *Psychosomat Med* 1954, 16, 414

> "We emphasise the fact that the diagnosis of chronic brucellosis *is in the hands of the physician*, and that *until some simple and reliable* ancillary investigation is elaborated, the results of the clinical examination of the patient should not be obscured by placing too much faith in bacteriological investigation."

Where this advice is not taken cases will continue to be missed. It is sad that a journal of your standing should contribute to the perpetuation of such mishaps.

Bath. HUGH WALLIS.

⁂ As we implied last week we were not certain that we had correctly extracted the information we wanted from the 35 detailed case-histories in Dr. Wallis' book, and we are grateful to him for these figures. But they do not dispel our doubts about accepting the skin test alone as the sole confirmatory evidence (in 12 cases), and it is hard to see how the passage from Barrett and Rickards' paper, with its reference to "previous or current" infection, answers the questions we raised about the significance of a fourfold rise in titre after injection of brucellin.

We assure Dr. Wallis that we were not offering "psychosomatic ailments" and P.U.O. as satisfactory diagnoses. No-one would deny that some patients whose illnesses remain unidentified under such labels have in fact got brucellosis, and Dr. Wallis has done an important service in emphasising this possibility. But he will not, we think, on the evidence in his book, persuade his readers—clinicians, pathologists, and others—that he has proved his point in anything like all the cases he records.—ED. L.

FATALITIES AND SPORT

SIR,—*Another rugby football fatality!!!* On Wednesday, Feb. 10, a 22-year-old student playing in an intercollege game was knocked unconscious in a tackle and died on Friday after being operated on for a brain injury. Do all the fanatical anti-boxing enthusiasts not agree and wish to raise their voices in protest to call for the abolition of this very dangerous and occasionally fatal sport? Or do they on the contrary wish to draw a veil over the incident and continue to regard boxing as the only sport which ever produces death?

London, S.W.16. F. H. TAYLOR.

PRIVATE PATIENTS IN THE NATIONAL SCHEME

SIR,—To those who have regarded the denial of free drugs to the private patient as a rank injustice your annotation of Feb. 13 comes as an unpleasant shock: the arguments sustained therein appear to me devious and of doubtful validity, but as one cannot doubt its essential integrity and freedom from political bias, I, like many others, are prepared to be further instructed.

How a private patient not registered on any doctor's list—thereby saving the country a capitation fee—making use of a private doctor's services in any way interferes with the service given by National Health practitioners is difficult to see, and likewise it is difficult to understand how such a doctor is to be regarded as having "entered the Health Scheme" by prescribing to his patient, under proper safeguards, those drugs which are the patient's right, having regard to the latter's contribution, often excessive, to the general body of taxation, out of which the Health Service is maintained.

If he does get better service, and this may not necessarily be the case, then the greater is the spur to see that facilities for patient care in the Health Scheme are improved and this tangible criterion is in my view infinitely worth preserving. If it was a case of too much money chasing too few goods (doctor's services) a case could be made, but as the supply of doctors is likely to exceed the demand, if present student entry is maintained, no strength is added to the argument on this score.

Again reference to the private hospital bed as an "apparent exception" can bring no joy to B.U.P.A. and other allied excellent schemes, as these provide for private nursing-home and private hospital bed facilities and for the private services of surgeons and specialists, and if argument as construed in your annotation is to be consistent then these schemes are against public policy. This I cannot believe, but if persisted in, I can only draw the conclusion that *The Lancet* is out of step with the views of the thousands of provident and thrifty people who support such schemes.

It could, of course, be argued that a doctor having a National Health practice and some private patients not registered with any doctor might be tempted to give a different level of service to the latter, but this surely does him a gross injustice, and in any case the annotation specifically refers to "purely private doctors."

Reference to "buying and selling" medical care merely confuses the issue: the fact is that services and drugs purchased with our money should be available to us as of right, and with it the right to make use of them in part or in whole as specifically promised by Mr. Bevan, when he became the first Health Minister, and this has been denied with a blatant cynicism which seems to afflict all Governments whatever their political colour.

London, S.W.1. ROBERT CUTLER.

SIR,—It is to be hoped that your annotation will produce more thought and discussion than was shown when this subject was last raised in the *British Medical Journal* in November, 1958. The importance of the issues has been more widely realised in the country now, and despite the Royal Commission report the subject will not lose its importance.

Your assessment of the most serious dangers of creating two standards of service in the N.H.S. is much in accord with our own, but since it is a complicated issue and various aspects are stressed we think it right to qualify and question some of your remarks. Firstly, the view, widely held by supporters and even some opponents of the proposal to provide drugs for private patients, that there is some injustice, is in our opinion erroneous. (We have no strong feelings about Private Practice as the Original Sin of Medicine.) It would be an injustice indeed if anyone were refused access to any one part of the National Health Service, but since in fact the Cohen committee—and age-old practice—have held that consultation and prescribing was one item of service, there can be no real grievance. Those who wish to avail themselves of the amenities of the Health Service must do so on the same terms as hold for the rest of the country. (In fact if you pursue the logic of your argument that having paid once people should not have to pay again, you can gather little solace that the hospital pay-beds are justly run. Those paying "full cost of treatment for private beds" are therefore overpaying and are also harshly treated since they have already paid for this part of the service.)

Secondly, the attitude of the British Medical Association membership is taken too readily for granted to be in support of drugs for private patients. The financial and social implications of the proposal are being more widely realised.

The main danger is, as you say, two standards of service. But you fail to bring out that with the inadequate general-practice organisation the N.H.S. would be even further undermanned in actual medical time, and consequently the second standard would necessarily be even lower than already exists. This is adumbrated in your statement that there would be "a vested interest in preserving the defects of ordinary medical care" Sectional interests would thus not only gain privilege but be actually operative in depressing the standards available for the community To establish the " rights " of the few, the " rights " of the many would be jeopardised if not actually sacrificed

A less easily defined but no less real danger would be the psychological effect on the faith of the country in the N H S "Nationalised" medicine would be the poor man's medicine Already one often hears " But I'm willing to pay for anything else", in spite of the fact that most general practitioners give their best and there is comparatively little private practice If this belief spreads it would be as calamitous for the profession as for the patient We would be divided into the poor doctors, and those who charge The vast majority of general practitioners have their future bound up with the N H S and any disparagement or deterioration of conditions in the Health Service will adversely affect the doctors no less

In addition, the desire to stimulate private practice (an avowed aim of the measure) will largely result in stimulating competition The cooperation and improved relationship which was noted since the inception of the N H S and the marked diminution of financial competition will once again increase The weary and slow progress to closer integration amongst general practitioners will be halted and group practice and health centres almost wholly obstructed

Even if the Royal Commission has envisaged possible changes that would be associated with increased private practice, it is doubtful if such a contingency could be fully covered—and would we then have a further inquiry?

The proposal of drugs for private patients is not merely important in itself, but would in fact emphasise and perpetuate some of the worse features that already exist in the N H S In few places in the world is there such a vast expenditure on the training of individual doctors, certainly nowhere do the doctors or the community reap such poor rewards in the exploitation of their skills The main defect of general practice is that it is in fact " Ancient Medicine in Modern Society "—and the rest of the health service organisation is based on the general practitioner!

In your leader,[1] Charges for Pay-Beds, you rightly observe "Reform would be a far more popular process if it never removed anything good until it had provided something better" The proposed changes can hardly be said to merit the title of " reform " There are dangers in venturing into the untried in organisation " Freedoms " and " rights " must not be cast away lightly, but so far in the profession we seem to have traded in the substance for the slogan (In what other circumstances would it be necessary or possible for an outside commercial organisation to set up relief working for doctors?)

Society can ill dispense with the traditional general practitioner, who has an important contribution to make, but we must devise ways of enabling him to meet his obligations to the community and encouraging him to make the contribution which his special knowledge and quondam skills qualify him The overcrowding and over-waiting in doctors' surgeries, and the overburdening of the doctor himself, will not be alleviated one jot by pressing for this measure

Birmingham

B BARNETT
M BARROW

SIR,—Your annotation was so appalling, and so obviously inspired by left-wing bias, that I have decided to cease taking *The Lancet*

For some years now your journal has done its best to produce disunity within the profession. My anger with it has been simmering for some time and I have now decided that the time has come for me to register my complaint by cancelling my banker's order

I might add that I run a large working-class practice and that I should probably lose slightly by the fact that my patients will still all remain N H S ones and that the central pool may be reduced if this injustice is put right It does not alter my conviction that it is grossly unjust and illogical to prevent drugs for private patients when these people are allowed their X-rays free, their hospital service free (including drugs!), and their domiciliary visits Why pick on drugs as an exception?

Space does not allow me to take up your foolish comments on the hospital beds being rented out by the N H S , your facts are not right here either No doubt in due course I shall read that there has been a take-over bid for your " rag " from the *Daily Mirror*

Shoreham-by-Sea,
Sussex

ANTHONY PARTRIDGE

SIR,—I am more than surprised at your assumption that the provision of " free " medicine for private patients would result in two standards of general practice Perhaps I am fortunate in my colleagues in Bristol, but I have not yet met one who gives less attention to his N H S than to his private patients In my own waiting-room nobody can distinguish the one from the other

As private practice keeps up one's standard for *all* patients a doctor will therefore automatically benefit his State patients

Bristol

H K V SOLTAU

SIR,—All concerned in improving the standard of general practice will welcome your courageous annotation Like good wine, the National Health Service will grow richer by increasing its own strength rather than by its dilution

London, N W 2

D S NACHSHEN

SIR,—I am surprised that *The Lancet* should indulge in such sophistry as the annotation last week on this subject The so-called apparent exception is an exception indeed The private bed in the public hospital rented at an empirical price enables the patient not only to buy the " personal care " of his consulting attendant but also to enjoy the full benefit of free drugs, dressings, and ancillary care which his attendant can prescribe The statement that payment for personal care within the National Scheme does not exist is only true so far as the general-practitioner service is concerned In practice it is available to any patient who elects to go under the care of a consultant fortunate enough to control private beds

London, W 1

JEROME STURRIDGE

⁂ To those who believe that medical privileges should not be purchasable within the National Health Service, the defence of private pay-beds in public hospitals can certainly sound a little sophistical We ourselves have continued to defend them on the ground that, so long as they cost the service nothing, they can be said to be outside it The wish to avoid having different standards of care within the service is not, of course, confined to people of particular political convictions

If the proposal were simply that " purely private doctors " should prescribe N H S drugs, we should be less troubled our objections, though we think them valid, might not be of much practical importance But an N H S doctor prescribing N H S drugs to someone registered with him as a private patient is unquestionably within the Health Scheme, and grave harm would be done if his patients began to transfer from his ordinary list to his private list in the hope of getting something better for a fee It is the amenities of the ordinary list, rather than those for the fee-paying patient, that the N H S has a duty to improve —ED L

---

Obituary

ROBERT HUTCHISON

Bt, M D, LL D Edin, Hon D Sc Oxon, LL D Birm,
Hon M D Melb, F R C P, Hon F R C P E

BEFORE the war we wrote "There can be few men alive today who have had a more intimate influence than Hutchison on the everyday practice of medicine, and he has achieved it largely by the direct impress of personality

"All over the world practitioners think of his precepts as they work at the bedside, their faces faintly reflect his smile as they remember his salted sayings, and they are daily saved from imprudence and humbug because they were taught by a man with a sublime gift for common sense"

Press Portrait Bureau

Twenty-one years later, his influence may have been attenuated by passage, but by those who knew him he will always be remembered not only as one of the great clinicians and teachers of our time, but as a man of individual character Having chosen his role, he played it with the touch of exaggeration needed to make his teaching memorable, and he enjoyed his prejudices But the ability, the wisdom, the clinical genius, were very real Moreover, the grave and the gay, severity and kindness, were so joined in him that he could raise standards yet be held in general affection

He was born at Kirkliston, Midlothian, and one account of him describes a boyhood classically austere, with excess of oatmeal and a four-mile walk to school Having the kind of early promise that is later fulfilled, he was Ettles scholar at Edinburgh University and senior president of the Royal Medical Society, graduating with first-class honours in 1893 In surgery those were still the days of the carbolic spray, and he afterwards recalled that almost his first duty as a dresser was to give an anæsthetic (chloroform) for a long abdominal operation—having never seen one given before

After house-appointments in Edinburgh, he worked in Paris and Strasbourg before becoming demonstrator of chemical physiology in the university In that post, and in 1896 when he took a house-appointment at The Hospital for Sick Children, Great Ormond Street, he produced the earliest of his many papers (a handlist of 276 was compiled by Dr White Franklin in 1951), his first subjects being the movements of the fontanelle, the state of maternal and fœtal blood at birth, estimation of the alkalinity of the blood, degeneration of brain cells, and, particularly, the chemistry and pharmacology of thyroid secretion He had a considerable record of research when in 1897 Leonard Hill invited him to The London Hospital as assistant in the physiology department In the residents' quarters at Great Ormond Street he had already planned and executed with Harry Rainy the first edition of their *Clinical Methods* which remains the guide of so many students, though its editors have changed With so many outstanding qualifications he was elected in 1900 to the staff of The London and also of The Hospital for Sick Children

Describing those far-off times, he has remarked characteristically that "looking back through the mist of half a century, we seemed to get on very comfortably indeed Whether the patients got on as well was, of course, a *totally different matter*" The wards presented a very different picture from those of today, with diseases generally in more advanced form, and four or five typhoid patients in each ward In the 1900s, he admitted, a medical ward was a rather depressing place, and the children's wards must likewise have been grim "Summer" diarrhœas, acute marasmus, and such deficiency diseases as rickets were appallingly prevalent in the East End, with its poverty and ignorance, and Hutchison could have found no more useful interest than nutrition and diet, to which he gave much thought At a time when authorities elsewhere were complicating the feeding of infants, he preached simplicity, saying that the infant's response is the only valid test of a feeding plan ("My dear boy, all that you need to know about infant feeding can be written on the back of a postage stamp") By one of his "premonitions", as Dr Langley Porter has called them, he made The London Hospital supply mothers with free cod-liver oil to add to the diluted sweetened evaporated milk which was all that many of them could afford for feeding their babies

In the early years of the century, Hutchison was one of a group of able men at The London who were rejecting the concept of the clinical entity, and, deeply influenced by the biological approach of the German school, were coming to think in terms of maladaptation to environment Arthur Keith and William Bulloch were his intimates, and there were many other stimulating people in the hospital—Leonard Hill, and Henry Head, and H M Turnbull among them (Turnbull used to relate that on their annual departure to the North for Christmas—in separate carriages—Robert attracted much attention as he paced the King's Cross platform in deerstalker cap, a long caped overcoat, and Mother Hubbard boots—the living image of Sherlock Holmes!)

Born to be a teacher, he reacted to his environment by writing further books, some of them in lecture form and several of them astonishingly successful *Hutchison's Food and the Principles of Dietetics*, still a standard work, started life in 1900, and *Lectures on Diseases of Children* in 1904 With Stansfield Collier (and later Reginald Hilton) he edited *An Index of Treatment* from 1907 This was the year in which, as an original member of the editorial board of the *Quarterly Journal of Medicine*, he contributed to its first number his famous paper On Suprarenal Sarcoma in Children with Metastases in the Skull Since 1910, when Homer Wright showed that the cells of these tumours arise from embryonic sympathetic nerve-cells in the medulla, the disease has been called neuroblastoma of the suprarenal medulla (Hutchison's type) In 1908 a handbook on *Applied Physiology* appeared, and in the later '20s it was followed by *Lectures on Dyspepsia*, his London Hospital lectures called *The Elements of Medical Treatment*, and *Some Principles of Diagnosis, Prognosis, and Treatment*

His ward rounds, with Hutchison a formal and often formidable figure in grey frock-coat, have often been described. What was most important about them, for student and houseman, was the sensitive way in which he dealt with patients, old and young, and the delicacy, the economy, and yet the completeness of his examination.

"To watch him examine an infant, especially one with pyloric obstruction, was an unforgettable lesson in clinical procedure. The gentleness, not only of his manipulations, but also in the spirit of his approach, made one feel that, without sentimentality, the man was alive with sympathy for the suffering child. ... He made his own demonstrations brilliant examples of what to do, and what not to do, in clinical examinations of the patient."

Again there was the frequent evidence of wide and up-to-date reading, so that new knowledge supplemented experience. Diagnosis and prognosis were brought to a fine art. In his earlier days at The London there were, of course, no reports from X-ray department or biochemical laboratory.

"You may say 'Well, in that case the diagnosis must have been very often wrong.' There, however, you would be in error. It was not, as a matter of fact, often far wrong. The object of diagnosis fifty years ago was chiefly to tell what would be found post mortem, and in that art the physician with his highly developed clinical instinct was extraordinarily skilful."

Dr Donald Hunter said that of all Hutchison's messages to his pupils this was the greatest—that as Medicine becomes more complicated good clinical method grows rather than lessens in importance.

It would be idle to pretend, however, that only his skill and shrewdness made these occasions memorable: there was also the fascination of watching someone different from anybody else, and listening to his fastidious utterance—fastidious and courteous even in his occasional invective. (Who, as a student, would not enjoy Hutchison's description of his Great Ormond Street clerks as "a curious collection of crapulous cretins creeping from crib to crib", or the comparison of his London Hospital ones to tabetic snails?) Like all good teachers, he took trouble to make his point memorably: when a certain type of squealing, kicking baby came into the outpatient department he would ask, "What is the treatment here?" and getting no answer would say, "Gentlemen, it is a clear-cut case of bromide for the mother." His lectures are full of pearls (as he would not scruple to call them).

"It is quite impossible that you should always be right in your diagnosis, if only for the reason that disease does not always play the game. It is better, however, to be wrong on sound principles than right by chance. Guessing is to be avoided at all costs, for if once you get into the habit of guessing you are diagnostically damned."

He believed in what some character in *The Wrong Box* calls "judicious levity"—a phrase that came beautifully off his tongue. Urging that nobody should ever start a lecture in his memory, he remarked: "There are better ways of commemorating the dead than by boring the living."

Naturally he himself was asked to give many lectures, including, at the Royal College of Physicians of London, the Goulstonians of 1904 and the Harveian oration of 1931. He was elected president of the college, in succession to Lord Dawson, in 1938, having previously been president of the Association of Physicians and of the Royal Society of Medicine. His scholarship and distinction of mind earned him the highest honours that Medicine can bestow, but in spirit he was neither an administrator nor a man of action and his main achievement was not in such offices. He was created a baronet in 1939 and spent the last part of his life at his home at Streatley-on-Thames. Even during his active years he had been a good deal disabled by a longstanding disorder. "Still," he wrote, "as a disease it has two great merits: (1) it is entirely painless, (2) there is no known treatment. I am therefore spared all modern therapy."

We conclude with a note from W. R. B.:

"Robert Hutchison's character was so complex that almost anything which it seems obvious to say about him needs qualification. He became a doctor before X rays were discovered, and retired from his hospitals at the beginning of the 1930s, before the major therapeutic discoveries of that decade had been made. An exponent of medicine as an art rather than a science, and a brilliant intuitive diagnostician, he had more in common with the 18th century than with the middle of the 20th. He was almost the last of a kind of physician now nearly extinct. Yet his early contribution to dietetics was scientific, and at heart he was far more of a scientist than he allowed his students to know.

"I am not sure whether he invented the classification of doctors into 'winduppers' and 'pooh-poohers', but I have heard him use it. He himself was a 'pooh-pooher' on the largest scale, but this, one felt, was a public persona which he had constructed by elaborating some of his native characteristics. Fortified by his gaunt and lanky appearance, his slow and dignified gait, a grey frock-coat, his Edinburgh accent, and his wit, it was a formidable facade, which might have made him admired and even a little feared. Yet he inspired, particularly in his colleagues and pupils, an affection which earned him the improbable diminutive, Bobbie. Relaxing in the staff-room after a ward round, he would put off the persona as far as he could, address one as 'My dear boy', and chuckle over some anecdote which was 'really very amusing'. Behind the mask there was, I think, a rather shy and lonely man, who, like an ancient Stoic, found life on the whole a bad thing one had to make the best of."

Another of his friends once put forward the opposite conclusion, saying that the pessimism was the mask, and behind it was a mind intellectually gay, with a cordial distaste for the dull. Both views could be sometimes right, for it was his complexity that made him so interesting a person.

Sir Robert Hutchison died at his Berkshire home on Feb. 12, aged 88. He married, in 1905, Lætitia Norah Moore-Ede, M.B. Lond., daughter of the Very Rev. Dr. Moore-Ede. Lady Hutchison survives him with two sons and a daughter. Mr. Peter Hutchison succeeds to the baronetcy. Sir Robert's brother, the late Sir Thomas Hutchison, was Lord Provost of Edinburgh in 1921-23.

In preparing this memoir we have drawn gratefully, though usually without acknowledgment, from tributes which appeared in the *Archives of Disease in Childhood* in October, 1951, and in the *London Hospital Gazette* at various times.

WALTER PATON MacCALLUM

C.B.E., D.S.O., M.C., E.D., M.B. Sydney, F.R.A.C.P.

Dr. MacCallum, consulting physician to the Prince Henry Hospital, Sydney, died on Nov. 22. He had held office in the Royal Australasian College of Physicians as honorary secretary from 1948 to 1950 and as honorary treasurer from 1950 to 1958.

During the 1914–18 war he served in the infantry and staff of the Australian Imperial Force in Gallipoli, Egypt, France, and Belgium and was awarded the M.C. and D.S.O. He was demobilised in 1919 with the rank of major, and returned to Australia to study medicine at the University of Sydney, and the rest of his medical life, apart from further war service, was spent in that city After qualifying in 1924 he held house-appointments, and in 1926 he joined the staff of the Royal Alexandra Hospital for Children In 1934 he was also appointed to the staff of the Royal Prince Alfred Hospital During the late war he served with the A A M C from 1940 to 1947 in Palestine, the Western Desert, Greece, Crete, Netherlands, East Indies, and the South-West Pacific In the later years of the war he acted as deputy director-general of medical services with the rank of brigadier, and for this work he was appointed C B E

He was elected F R A C P in 1946, and his published work included papers on rheumatic fever and meningitis in childhood '

A colleague writes

" MacCallum belonged to one of the outstanding families in New South Wales, and had, himself, a first-class mind and an attractive manner He was one of the group of senior physicians who guided the Australasian College along sound lines in its early critical years "

JAMES IGNATIUS ENRIGHT

B A , M D R U I

Dr J I Enright died on Jan 13 in Dublin In the 1914–18 war he took part in investigations on pellagra among prisoners-of-war in Egypt

He was educated at a Jesuit College and the Royal University of Ireland He graduated M B with honours in 1914. After holding resident appointments at the Eastern Fever Hospital, Homerton, and the Royal Sussex Hospital, Brighton, he became medical officer in charge of a prisoner-of-war hospital in Cairo On his return to Ireland he settled in practice at Dalkey, where he was born

P. H M-B., who worked with him in Cairo, writes

" Enright was then a young, impulsive, loquacious, and witty Irishman with an inquiring mind Among the wretched, emaciated, and half-starved Arabs and Turkish prisoners he found much to interest him Pellagra had just made its appearance in many strange and unforeseen guises, and he became familiar with pellagra typhus, and many peculiar actinogenic eruptions on the face, hands, and legs, as well as œdematous swellings Later he reported these observations and also an equally instructive outbreak of pellagra in the seemingly well-fed and nourished Austrian and German prisoners during 1917 and 1918 (The paintings which were made for him by an Austrian sergeant, who was by trade a sign-painter, are now in my possession) He also described an unrecorded fatal urinary infection with *Bacterium coli* which was traced to miliary cortical abscesses in the kidneys.

" Ignatius was a fluent and entertaining speaker, with a delightful brogue, and he could quote at length from Latin and English literature Warm-hearted and generous he was a staunch and loyal friend, and his sudden, unexpected eruptions into the metropolis were always welcome "

DR. WU LIEN-TEH

W C W N writes

" Wu Lien-Teh was a remarkable man for he was able to enjoy the best of both worlds—the East with its wisdom and the West with its scientific practice He held fast to the traditions and philosophy of his forebears despite the many years he spent in Europe and the United States

" I have reason to be grateful to him for his advice and kindness when I found myself, an occidental, in the orient We had a common interest in that we graduated from St Mary's Hospital, and when he visited Hong Kong he would reminisce on his happy student days at Cambridge and in London He was ever grateful for the friendship of Sir Zachary Cope and Prof T R Elliott

" Most of us start contemplating retirement after the age of 60, but not Wu Lien-Teh I travelled with him and his family in 1937 from Hong Kong to Singapore after the Japanese had overrun Shanghai His beautiful home and valuable collection of ancient Chinese medical books had been burnt I recall his fervour when he said 'I am 60 and have lost everything but I shall not give up medicine I shall open a dispensary in Malaya ' Ironically he was to suffer from the Japanese again a few years later when they occupied Malaya Undaunted he started to practise again after their defeat

" He more than any other Chinese, laid the foundations of a modern medical service for his country. It is fortunate that posterity will have in his autobiography—*Plague Fighter*—a record of the achievements of this great doctor "

DR. EILEEN HICKEY

P F writes

" Several generations of students of the Belfast School of Medicine were well acquainted with Dr Hickey's tireless energy in social, religious, and political fields, but it is as a clinical practitioner, teacher, and adviser that she will perhaps longest be remembered

" As a clinician she was infinitely patient and painstaking, shrewd and wise Her experience extended over four decades of change, and she could accept with equanimity the encroaching tide of medical advance, with its bright if rather brittle purveyors of the ' scientific approach ', absorbing the principles as a good doctor should, but never losing her sense of perspective The student body were ever her particular concern their deportment, manners, dress—little escaped her vigilance, and on their application and training she often expressed herself strongly Her clinical clerks usually found that she did not suffer fools gladly, but they left her firm richer and wiser for the experience

" For some time she had been troubled by a partial deafness, but this affliction only sharpened her clinical acumen 'Had I my way,' she snorted to a student, advancing on a patient whilst producing the inevitable stethoscope, ' that instrument would be banned during your first clinical year then perhaps you would use your eyes ! ' Or again ' We make mistakes, not because we don't know, but because we don't look.' She looked and saw her patients, as well as their illnesses, she saw her students as beginning an odyssey, she saw her profession in its nobility, and her life as an opportunity to serve "

Parliament

Scottish Mental Health Bill

On Feb 9, in introducing this Bill, which has already been briefly described in our columns,[1] Mr **John Maclay**, Secretary of State for Scotland, said that it had three main threads, to retain the best features of the existing law, to weigh the balance wherever there was doubt in favour of the liberty of the subject, and to devise a code which was in harmony with authoritative medical opinion.

Miss **Margaret Herbison** welcomed the Bill on behalf of the Opposition with two reservations She regretted that responsibility for the training and occupation of the so-called "ineducable " children should be transferred from the education to the health authorities, and she was uneasy that the local authorities' powers to provide community mental-health services were only permissive and not mandatory These new services would place a heavy burden on the authorities and she asked what financial help would be given to them.

Uncertainty about the local-authority services was a recurrent theme in the debate (which was interruped for three hours for a discussion on the breakdown of the Cyprus talks) Mrs **Judith Hart** pointed out that the authorities already had most of the powers necessary to give community care to the mentally ill and the mentally defective, but made disappointingly little use of them For instance, out of 49 Scottish county councils and large boroughs only 1 had appointed a special committee to deal with mental health Too few child-guidance clinics had been provided, and those that existed often had no consultant psychiatrist or psychiatric social worker on the staff. There were only 2 senior medical officers in Scotland engaged wholly in mental-health work. Of the 118 welfare and mental-welfare workers in the Scottish counties 70 were also district clerks, and probably only half their time could be given to their mental-welfare duties 5 psychiatric social workers were employed in the whole of Scotland, but not all 5 were fully qualified Mental-health work would not progress until the authorities' powers were translated into duties

Dr **J Dickson Mabon** suggested that if the Government persisted in their present attitude towards finance we should be no better off with the passage of the Bill For twelve years the local authorities had had permissive powers, and the Secretary of State had been able at any time to direct that they should become duties Yet the Fyfe Committee had severely criticised the administration of the mental-defective service in 1957 and precious little had been done since

Mr **T G D Galbraith**, joint under-secretary of State for Scotland, said that the Bill set the legal foundation for the things to be done in terms of care, treatment, and aftercare. It did not itself provide the accommodation or recruit the workers These services were all the responsibility of various agencies, and the Bill laid down only the law under which they would work. Therefore, it did not require substantial new charges They looked to the local authorities to play a large part in the expansion of the mental services outside the hospitals and within the community The expansion would certainly involve considerable expenditure, and he assured the House that it would be taken into account in the discussions on the general grant for local authorities which would be held later this year He recognised that this arrangement did not altogether satisfy all hon. Members and that there might be differences of opinion as to the best way of financing local-authority services

There were several reasons, he continued, against making the local authorities' powers permissive rather than mandatory Not all authorities had the same potential for expansion, and any statutory duty would therefore have to be limited to what the smallest authority could manage If local democracy was to mean anything authorities must at least be given the chance to exercise initiative Again, for the rest of the health service the authorities' powers were permissive, and the Government was anxious that the mental and physical health services should be treated in the same way Dr **Mabon** pointed out that the mental-health services were not at the same stage of development as these for physical health But Mr **Galbraith** maintained that we must have permissive powers for both at a time when we were trying to make the two types of medicine comparable

QUESTION TIME

A Seat in the Cabinet?

Mr **L A Pavitt** asked the Prime Minister if, in view of the negotiations with the medical profession following the publication of the report of the Royal Commission on Dentists' and Doctors' Remuneration and the importance of the Government's decisions arising therefrom, he will enlarge the Cabinet by the inclusion of the Minister of Health Mr **R A Butler** replied The hon Member would be wrong if he thought that, because the Minister of Health is not a member of the Cabinet, the Government will give less than due attention to the questions raised by this report. Mr **Pavitt** Will the Leader of the House urge the Prime Minister to take into consideration, not only the Government's position *vis-a-vis* the Minister, but, in view of these negotiations with the medical profession, the need for confidence on the other side in the negotiations if the outcome is to be satisfactory? The report may well set the pattern of the family doctor service for the next twenty years The way in which previous negotiations were carried on destroyed the confidence of the medical profession This single act perhaps would be sufficient to restore confidence in the Government. Mr **Butler** The hon Member's question will have done a service if it draws attention to the fact that the Government attach the greatest possible importance to this Commission and to the findings I can assure the hon Member and the House that this matter will be treated by the Government as one of the first importance

New Drugs

Mrs **Harriet Slater** asked the Minister of Health what proposals he had for controlled research and testing of new drugs before they were sold without a doctor's prescription — Mr **Derek Walker-Smith** replied While there are powers which enable supply to be permitted only on medical advice and prescription there is no authority under existing legislation for this requirement The Committee on the Cost of Prescribing has, however, made a recommendation that all new drugs should be subjected to clinical trial, and I hope soon to be able to reach a decision on it.

Drugs for Private Patients

Dr **Donald Johnson** asked the Minister what undertaking was given by the British Medical Association, in making its representations to him last year about the desirability of supplying drugs under the National Health Service to private patients, to cooperate in the administration of safeguards against over-prescribing on the part of private doctors — Mr **Walker-Smith** replied In discussions with officers of my department on the possibility of making the kind of financial and administrative arrangements which would be required if it should be decided as a matter of policy to introduce legislation, the Association agreed to safeguards on similar lines to those applying under the National Health Service

Sabin Oral Vaccine

Mr **W G Clark** asked the Minister whether it was intended that there should be trials of Sabin oral poliomyelitis vaccine in this country —Mr **Walker-Smith** replied The Medical Research Council will shortly be carrying out small-scale trials of this vaccine in selected areas and I am asking the local health authorities concerned to give their full cooperation.

Employment of Disabled

Of the 695,000 registered disabled just under 60,000 were registered as unemployed in January

---

[1] See *Lancet*, Jan. 30, 1960, p 290

Control of Drugs

The Poisons Board have recommended that the following substances, as well as 'Preludin', should be made available only on medical prescription

- Acetylcarbromal
- *Androgenic and œstrogenic substances, the following
  - Benzœstrol
  - Steroid compounds with androgenic or œstrogenic activity, their esters
  - Derivatives of stilbene, dibenzyl or naphthalene with œstrogenic activity, their esters
- Azacyclonol, its salts
- Benactyzine, its salts
- 3-Benzylhydrazinocarbonyl-5-methyl*iso*oxazole, its salts
- Bromvaletone
- Captodiame, its salts
- Carbromal
- 2-*p*-Chlorophenyl-3-methylbutane-2 3-diol
- Guaiphenesin
- 4-Hydroxymethyl-2 2-di*iso*propyl-1 3-dioxolan
- Hydroxyzine, its salts
- Imipramine, its salts
- Mephenesin, its esters
- Meprobamate
- Metformin, its salts
- Methocarbamol
- α-Methyl-phenethylhydrazine, its salts
- Methyl phenidate, its salts
- Nialamide, its salts
- Phenelzine, its salts
- Phenformin, its salts
- Pipradol, its salts
- Rauwolfia, alkaloids of, their salts
- Thalidomide, its salts
- Zoxazolamine, its salts

* Except preparations intended for use in external applications and animal feeding stuffs

Medicine and the Law

Probation for Schizophrenic

AN 18-year-old youth, who pleaded guilty to stealing over £15,000 from the city treasurer's department at Norwich whilst employed as a clerk there, has been put on probation for three years [1]

Dr William Abel, of Hellesdon Hospital, said in evidence that the youth was a typical schizophrenic The prison medical officer, Dr B M Tracey, agreed with most of Dr Abel's findings

In putting this offender on probation, Mr Justice Byrne said "You have pleaded guilty to an extremely serious offence which would merit many years of imprisonment in normal circumstances But two doctors agree that you are mentally ill If I sent you to prison, you would probably become a criminal"

It is a condition of the probation that he goes to a mental hospital for twelve months

No Home for an Epileptic

The policy of the courts in dealing with first offenders is to avoid giving a prison sentence unless this is clearly indicated by the seriousness of the offence or for some other reason It is strange, therefore, that the Nottingham magistrates should have found that they had no option but to remand a pregnant woman suffering from epilepsy to prison for three weeks for what may be described as welfare reasons

The woman, aged 27, had pleaded guilty to stealing £12 10*s* from a wallet in a shop [2] She took the money, handed the empty wallet back to the owner, and later took most of the money back and said she had spent £1

On her third appearance in court, it was reported that four epileptic colonies had refused to have her because of her pregnancy, and a mother-and-child home had refused to have her because she was considered unstable in view of the epilepsy Her husband had been sentenced to two years' imprisonment three days after they married

Ordering that the case should be sent to the Home Secretary, the chairman of the bench said that there had been "a grave lack of responsibility on the part of certain branches of the medical services" Remanding the woman to prison was the only way of ensuring that she received proper medical attention

Diary of the Week

FEB 21 TO 27

Monday, 22nd

Notes and News

EFFECT OF RADIATION ON HUMAN HEREDITY

In some widely scattered areas of the world the level of natural background radiation is well above that in other parts of the world, and properly planned studies of the populations in such areas could make significant contributions to knowledge of the genetic and somatic effects of prolonged exposure to low levels of radiation The recent report[1] of the W H O expert committee on radiation surveys the known areas of high background radiation and sets out the principles of planning investigations of such areas The Kerala area, at the southernmost extremity of the west coast of India, is probably the only area now known which might be profitably investigated, and the last part of the report is devoted to the application of the general principles to the planning of what is called "the Kerala project"

Comparison of specific mutant phenotypes in the irradiated and control populations will rarely be feasible, and reliance will usually have to be placed on a comparison of populations with respect to those characteristics that are assumed to reflect the cumulative effect of mutation at many loci The committee make a number of suggestions concerning information to be collected in the Kerala project, with particular reference to the ad-hoc census that would have to be the first step, and a brief section of the report is devoted to the estimated requirements in men and material

HOSPITAL PLANNING AT WOLVERHAMPTON

The Birmingham Regional Hospital Board and the Wolverhampton Hospital Management Committee have been considering plans for the expansion of hospital services in the Wolverhampton group A scheme has been proposed by which the number of beds at the Royal Hospital will be reduced to about 250 and the hospital will become a centre for casualties and outpatients on the lines of a policlinic with some inpatient beds The orthopædic department and some orthopædic beds will remain and other services will include radiology, physiotherapy, and pathology A new radiotherapy department will be added, with a cobalt unit and isotope and physics department There will also be some radiotherapy beds in the main block The 4 new operating suites, which are at present being designed, will be retained and there will be some beds for the following thoracic surgery, neurosurgery, plastic surgery, the burns unit, outpatient investigations, and dentistry and orthodontics The main inpatient service will eventually be moved to the site at New Cross, where it is proposed to adapt six wards to provide an acute admission and rehabilitation geriatric unit, and to build a new maternity unit. It is also planned to build on this site a mental hospital with 350 beds and a new general hospital Once these new buildings are erected some of the smaller hospitals and units of the group, some of which are uneconomic, can be closed

LIPIDS AND ARTERIAL DISEASE

Few medical men find time to study Professor Hilditch's large book on *The Chemical Constitution of Natural Fats*, which is a standard reference work for chemists, but now, with Dr Jasperson, he has produced a small monograph[2] which can be strongly recommended for those with only an evening to spare. It contains a clear account of the distribution of fatty acids in Nature, and also of *cis-trans* isomerism—aspects of organic chemistry that most medical students in the past have skipped with impunity Nowadays, without some accurate knowledge of these subjects, it is impossible for a doctor to discuss critically with a patient the latest piece of dietary advice for those with ischæmic heart-disease This summary by Professor Hilditch and Dr Jasperson is a first-class piece of teaching, suitable for both undergraduates and postgraduates

SCIENTIFIC RESEARCH IN SCHOOLS

Three years ago the Royal Society set up a committee on scientific research in schools, with Sir Lindor Brown as chairman Its second report shows that last year 48 schools were doing research under its auspices, receiving over £2000 in grants All projects are carried out with the specialist advice and assistance of fellows of the society and of others who act as advisers The committee "has been much stimulated by the continued and growing response to this scheme" and looks forward to receiving further requests from schools

EQUIPMENT FOR THE DISABLED

The National Fund for Poliomyelitis Research is sponsoring a reference book entitled *Equipment for the Disabled*, and it is hoped to publish it in August.

The book will be in loose-leaf form to allow later additions and deletions, and on each separate sheet there will be a photograph, written description, and, where necessary, working drawing of the apparatus

The work of collection and preparation of material for publication is being carried out at the Nuffield Orthopædic Centre, Oxford, by Dr Margaret Agerholm, with the collaboration of Miss E Hollings and Miss W Williams, and she will be grateful for suggestions from colleagues for the inclusion of special apparatus which they have found useful

INCREASES IN SERVICE PAY

The increases in pay for those in the Services, announced last week,[1] affect medical officers as follows

Rank (Army only)	*Annual basic pay when first appointed*	
	Old	*New*
	£	£
Lieutenant	657	730
Captain	766	839
Major	1295	1387
Lieut -Colonel	1660	1806
Colonel	2080	2244
Brigadier	2354	2573
Major-General	3029	3285
Lieut.-General	3759	4124

Retirement benefits have also been improved

University of Cambridge

Dr E H R Ford has been appointed lecturer in anatomy and Dr R H Adrian lecturer in physiology

Royal College of Surgeons of England

At a meeting of the council on Feb 11, with Sir James Paterson Ross, the president, in the chair, Prof John Bruce was admitted and Prof Carl Semb (Oslo) elected to the honorary fellowship, and the honorary medal of the college was awarded to Sir Cecil Wakeley, past president

Mr J D T Jones, Mr R G Macbeth, and Mr A G Cross were admitted to the court of examiners Dr Cuthbert Dukes was appointed Thomas Vicary lecturer for 1960, and a Hunterian professorship was awarded to Mr P M. Weston (West Indies) Dr Bertram Cohen was appointed the first Nuffield research professor of dental science and Dr G V R Born Vandervell professor of pharmacology

The following were elected to the fellowship *ad eundem*

Isabella Forshall, P G Cutlack Martin, G E Moloney, A W Kay

Diplomas of fellowship in the Faculty of Anæsthetists were granted to the following

K W Dodd, G B Burchell, I M Brown, T K Hardy, N H Eve, M R Milne, William Braude, W S Dykes J N Thorpe, I W Davidson, Sohrab Rustomji Umrigar, R D Davie, Nasir Husain Jafry, P W McCormick Mary F West, Catherine K Adam, Gordon Clarke, D T McClements, Marie M Simpson, W J Colbeck, Winifred E Elesh, C J R Elliott, J P N Hicks, A B Lodge W N C McCleery, Norman McLeod, D D Moir, E D T Ross, P A Tsoi-A-Sue, D M Davies G C Fisk, Dorothy E Harris, D D Hart, P J W Knell, I M J Mair, R R Manning, Isobel Speirs, Lakshman Tisse Wijeyaratne, F B N Clarke, A T R Fuller, C F Hider, B A Lyder, Maung U Win, J H Stevens, T H Taylor, R J Thomson

Licences to practise and the diplomas mentioned in our issue of Feb 6 (p 344) were conferred jointly with the Royal College of Physicians In addition a licence to practise was conferred on Patricia S Stephenson and the D M R T was conferred on D S Andrew and K D Neddy

---

[1] Service Pay and Pensions Cmnd 945 H M Stationery Office Pp 40 2*s*

University of Aberdeen

The following appointments have been made

Dr A H C Sinclair-Gieben, senior lecturer in mental health, Dr N G Fraser, lecturer in mental health, Dr D C Burke, lecturer in biological chemistry, Dr John Findlay, lecturer in anatomy

Royal College of Physicians of London

Dr J D N Nabarro will give the Oliver-Sharpey lectures on Tuesday and Thursday, March 8 and 10, at 5 P M, at the college, Pall Mall East, S W 1 He will speak on the pituitary and adrenal cortex in general medicine

University of Birmingham Medical School

Prof J Z Young will give the William Withering lectures on Monday, Tuesday, and Wednesday, May 2, 3, and 4 He will speak on mechanisms of learning and form discrimination On Wednesday and Thursday, May 18 and 19, Sir Dugald Baird will give the Ingleby lectures He will speak on the evolution of modern obstetrics All the lectures will be given at 5 P M at the Medical School, Birmingham, 15

Horder Memorial Trust

The trustees of this memorial to Lord Horder have decided to offer a travelling fellowship every third year, of the value of £600, to enable a senior member of the medical profession to visit Commonwealth countries It is also hoped that he will give a lecture at St Bartholomew's Hospital or the Royal College of Physicians The first appointment is likely to be in 1961. It is not proposed to advertise the fellowship but the trustees will appoint a selection committee early in October The secretary of the Trust is Dr E M Darmady, Central Laboratory, Milton Road, Portsmouth

Rockefeller Foundation

During the fourth quarter of 1959 the Foundation made grants of over $12 million Those for medical and natural sciences amounted to nearly $6 million These included a three-year appropriation of £24,000 (about $69,000) to the London School of Hygiene and Tropical Medicine for investigations into protein malnutrition

At the school's human nutrition laboratory and at the human nutrition research unit of the Medical Research Council the protein content of tropical foodstuffs is being studied By experimentally producing in animals two of the severe types of protein malnutrition which occur in man, it has proved possible to bio-assay vegetable proteins for the prevention and cure of protein deficiency A technique for expressing in quantitative terms the protein values of foods consumed by man has been developed and is being used to establish requirements of the aminoacids essential to growth and health The supplementation of deficient diets with vegetable protein sources, such as legumes, leaf proteins, and flour residues, is also being investigated

The Doctors' Window in Guildford Cathedral

At a meeting of the Guildford division of the British Medical Association last week, Dr G I Watson, chairman of the Doctors' Cathedral Window Fund, handed a cheque for £1000 to the secretary of the Guildford New Cathedral Council

The Society of Apothecaries contributed 55 cheques totalling £268 and the B M A £105 centrally with a further £40 from the Surrey divisions £143 was contributed by medical staffs of London teaching hospitals, while gifts from other corporate bodies totalled £104 Donations from 352 individual doctors at home and overseas amounted to £642

Miss Moira Forsyth, the artist who made the window, was thanked on behalf of the medical profession by Dr S Keys, chairman of the division The stained glass panels are now on display at the cathedral

Laboratory Animals Centre

This centre will hold a congress at the University of Nottingham on Monday and Tuesday, April 11 and 12 A symposium on the provision of animals for cancer research will be held at 1, Wimpole Street, London, W 1, on Monday, May 23 Further particulars may be had from the secretary of the centre, M R C Laboratories, Woodmansterne Road, Carshalton, Surrey

Medical War Relief Fund

During 1958–59 six educational grants amounting to £984, and seven maintenance grants amounting to £710, were made During the past year repayments of £1000 have been made

Biometric Society

This society will hold a symposium in Leyden from May 10 to 13 on quantitative methods in pharmacology Further information may be had from Mr H de Jonge, department of statistics, Nederlandsch Instituut voor Praeventieve Geneeskunde, Wassenaarseweg 56, Leyden, The Netherlands

Community Care of the Mentally Handicapped Child

The Metropolitan region of the National Society for Mentally Handicapped Children will hold a conference on this subject at Church House, Westminster, S W 1, on Saturday, March 12, at 2 45 P M Further particulars may be had from the hon secretary, Mr E R Skoyles, 194, Kenmore Avenue, Kenton, Middlesex

Mental Patients and the Disabled Register

Regulations made last year have removed the automatic bar to the admission to this register of all patients in mental hospitals or institutions These patients are now eligible for admission, provided they are able to work, even though they still remain in hospital This change was recommended by the Piercy Committee

Hunterian Society

The annual dinner, commemorating the 232nd anniversary of John Hunter's birth, was held in London on Feb 11

The toast of the Society was proposed by Sir Cyril Hinshelwood, president of the Royal Society, who said he was proud that Hunter had been a fellow of the Royal Society, for, although he would have been unorthodox in any age, the key to his greatness lay in his ability to see problems in their largest possible context and in terms of basic principles In his reply, Mr Alec Badenoch, the president, welcomed the guests, thanked the officers of his society, and reviewed the year's activities which had been popular rather than scientific, for, like Hunter, the society was unconventional

Dr Kenneth Robson, proposing The Lord Mayor and Corporation, spoke proudly of the society's link with the City and its privilege of using the Mansion House for the annual oration The Lord Mayor, Sir Edmund Stockdale, responded

Dr Clement Chesterman proposed The Guests and Kindred Societies In thanking the society on behalf of the " non-Hunterians " Lord Radcliffe said he was delighted to feel that he had been invited " as a person and not as a report " He went on to recall that Hunter had been one of the first expert medical witnesses to appear in a murder trial, when he had been criticised by the judge for being unable to answer " yes " or " no ", but, Lord Radcliffe added, this was a very bad judge

Dr D A Pond will give a lecture for general practitioners at University College Hospital, London, S W 1, on Sunday, March 6, at 10 15 A M He will speak on new stimulants and tranquillisers in psychiatry

Births, Marriages, and Deaths

DEATH

TAYLOR —On Feb 15, Dr James Maberley Taylor of 17, Kent Terrace, London, N W 1

PLACENTA PRÆVIA*

C H G MACAFEE
M.B Belf, F.R.C S, F R C S I, F.R C O G
PROFESSOR OF MIDWIFERY AND GYNÆCOLOGY IN
THE QUEEN'S UNIVERSITY OF BELFAST

PLACENTA prævia has long been recognised as one of the most dangerous complications of pregnancy Just over a hundred years ago, the maternal mortality from this cause was 30% and the fœtal mortality 60% By 1939, the maternal mortality had dropped to 5%, but the fœtal loss was little changed at 54% In 1945–50 the modern views on the treatment were widely described, and in the middle '50s the maternal mortality again fell appreciably In some centres the perinatal fœtal mortality has now been reduced to around 10%

One reason for this improvement is that the attitude of both doctors and midwives towards antepartum hæmorrhage has altered They no longer look upon it as a surgical emergency which must be dealt with immediately in the patient's own home. Hence in the vast majority of cases the patient is transferred to hospital without any attempt to confirm the diagnosis of placenta prævia by vaginal examination This fact is evident from the Oxford and Belfast series in table I, which are shown in contrast to an Indian series (Qureshi 1953) where 80% of the deaths were in women who had been examined before admission

TABLE I—THREE SERIES COMPARED

Series	No of cases	Maternal mortality	Perinatal mortality	Cæsarean section	No of examinations
R.M.H. 1946–53	200		11 9%	76%	2
Oxford 1948–59	217		9 7%	66%	
Qureshi 1934–45	200	30 (*15%*)	67%	16%	24

R.M.H. = Royal Maternity Hospital, Belfast.

Nevertheless, avoidable deaths are still occurring The report on confidential inquiries into maternal deaths in England and Wales 1952–54 shows that even within recent years the profession in England and Wales has not fully appreciated the essentials of treatment During those three years 29 women died as the result of placenta prævia, and avoidable factors were considered to be present in 55% of these

> "There were often several avoidable factors in one case, a common combination being failure to anticipate trouble, in that anæmia was left untreated, warning hæmorrhage ignored or women of high parity booked for home confinement, then when hæmorrhage occurred, sometimes in a patient already unlikely to withstand it, the action was hesitant or plainly ill considered."

Today there should be no hesitation about transferring any case of antepartum hæmorrhage to hospital There are few exceptions to this rule, and I shall deal with them later

It should surely be obvious that a premature vaginal examination may precipitate a hæmorrhage. Such a hæmorrhage may necessitate immediate treatment, irrespective of the duration of the pregnancy This means an additional risk to both mother and baby

The next improvement has been the more general adoption of expectant treatment We have long since got over Jaggard's dictum that "there is no expectant plan of treatment for placenta prævia"

Duration of Pregnancy

When a patient is admitted with antepartum hæmorrhage, the duration of pregnancy must be taken into account

1 If the pregnancy has reached 37–40 weeks, delay in treatment is unwarranted Having typed the patient's blood and determined the hæmoglobin level, one should not fail to make a diagnosis of the cause of the hæmorrhage Examination of the abdomen will go a long way towards confirming or disproving the diagnosis of placenta prævia If the presenting part is high, the fœtal heart (even after a moderate hæmorrhage) is undisturbed, and the uterus is not tender, the patient probably has a major degree of placenta prævia. If the presenting part is easily felt above the symphysis pubis and tends to overlap it, the placenta is posterior, while if the head is not easily felt unless the examining fingers approach it from either side, the placenta is in front

The final answer can be given by a vaginal examination, but this should be done only with the patient on the operating-table Such examinations have been criticised, but unless the position of the placenta is accurately determined many unnecessary cæsarean sections will be performed.

If the first episode of bleeding has been at 30–34 weeks, expectant treatment plays an important part The object should be to avoid any active treatment until the patient has reached 37–38 weeks, but whether this can be achieved depends on her behaviour from day to day. The attendant's hands may be forced by the recurrence or persistence of bleeding of such degree that delay in treatment would jeopardise life Though spontaneous catastrophic hæmorrhage is extremely rare—so rare that Dr Herman Johnson in the U S.A felt confident enough to challenge anyone to produce a case—persistent or repeated small hæmorrhages may result in serious maternal anæmia.

During expectant treatment, measures should be taken to improve the patient's general condition, and blood-transfusion may often be required to correct anæmia quickly

Evidence of the value of expectant treatment is given in table II, which analyses series of cases collected from hospital reports

To show that the 75 cases in Belfast were not loaded favourably with mature babies I should point out that 25 of the 75 patients had their first hæmorrhage before the 30th week. In these 25 the shortest time between admission and treatment was twelve days and all were delivered of live babies Unfortunately, 3 of these died in the neonatal period, but even in this unfavourable group the fœtal mortality was only 12%

TABLE II—MORTALITY IN RELATION TO EXPECTANT TREATMENT

Series	No receiving expectant treatment	Fœtal mortality	Maternal mortality
1553	257 (*16 5%*)	14 7%	0 79%
1353	187 (*13·8%*)	20·8%	1·07%
200 (R.M.H)	75 (*35%*)	8 5%	

---

* From a lecture given at Queen Charlotte's Hospital, London, on Sept 25, 1959

7122

X-ray Diagnosis

It is in cases of antepartum hæmorrhage at 30–37 weeks that X-ray diagnosis may be of assistance. At this stage accurate clinical diagnosis can be difficult unless the fœtal head is deeply engaged, although a thin placenta prævia may not prevent engagement. With modern radiological techniques the placenta can be located in a fairly high proportion of cases, but one must remember that with placenta diffusa or membranacea, or a placenta on one side of the lower uterine segment, the X-ray appearances can be frankly misleading. If in doubt, the case must be treated as one of placenta prævia until 37 or 38 weeks.

In the discussion on placentography at the Royal Society of Medicine in January, 1959, very diverse views were expressed. Some teachers would use placentography in all cases of antepartum hæmorrhage, or a high free head, whereas others regard it as quite unnecessary or even "dangerous nonsense". Personally I am relieved to find that even some of its earlier advocates have now discarded this type of examination. In my hospital placentography has not been done for some years, and X-ray pelvimetry is almost a thing of the past. In the course of the discussion Dr. Blair Hartley said:

> "I do not accept that adequate placentography can be carried out using only a single lateral view with the patient lying down (as has been claimed). Even with four films, carefully planned, really adequate opinion is, not infrequently, very difficult to offer, even in expert hands." (Hartley 1959.)

Coming from a radiologist, and an advocate of placentography, I would regard this as complete condemnation of this method of examination. As an obstetrician Mr. John Stallworthy said:

> "The idealistic goal which had been set in the treatment of placenta prævia over ten years ago, namely, that there should be no maternal deaths and an uncorrected fœtal wastage of 10 per cent or less, had been achieved, but in doing so it *had been found that the radiological diagnosis was seldom necessary.*"

Four possible causes of the bleeding have to be considered:

1. Placenta prævia.
2. Separation of a normally situated placenta.
3. Hæmorrhage from a circumvallate placenta.
4. Toxic accidental hæmorrhage in a patient with a placenta prævia.

The other local causes of antepartum hæmorrhage—e.g., cervical polyp and carcinoma of cervix—should be excluded by passing a vaginal speculum and inspecting the cervix.

Percival and Murray (1955) maintained that soft-tissue placentography could reduce the use of valuable antenatal beds for cases of antepartum hæmorrhage. They wrote: "In non-toxic accidental hæmorrhage, once placenta prævia has been excluded and bleeding has ceased, the patient can be safely sent home." I am afraid I cannot agree with this, for even non-toxic accidental hæmorrhage seems to carry a fœtal mortality higher than that of placenta prævia treated by modern methods. If I am right, the differentiation between non-toxic accidental hæmorrhage and hæmorrhage from placenta prævia is of little practical value at this period of gestation, since the patient should *in any case* be retained in hospital for investigation and observation.

The circumvallate placenta is often associated with small recurrent antepartum hæmorrhages, but several other features help in the diagnosis. The uterus seems smaller than the period of amenorrhœa would suggest, the baby is small, and the presenting part is usually well engaged. In addition, placentography may demonstrate the placenta in the upper uterine segment, and there is no evidence of toxæmia.

TABLE III—MORTALITY IN RELATION TO CÆSAREAN SECTION

Series	—	Perinatal mortality	Maternal mortality	Cæsarean section
R.M.H.	1937–45	22%	0.52%	41.3%
	1946–53	11.9%		70%
	1954–58	12.5%	1.5%	67.7%
Oxford	Last 217 cases	9.7%		66%
Qureshi	1931–39	71.3%	21.9%	8.8%
	1940–45	60.2%	5.8%	26.7%

Association of a placenta prævia with a toxic accidental hæmorrhage does raise difficulties in diagnosis and treatment, but it is a possibility that must be considered where a patient with an undoubted placenta prævia has gross albuminuria and perhaps hypertension.

Treatment

The patient who has had a long spell of expectant treatment has the scales weighted heavily in favour of cæsarean section as the method of treatment most likely to result in a living child. Table III, setting out results in several series, suggests that both maternal and fœtal mortality are lower where the operation is performed often.

In Qureshi's Indian series one would have expected a much greater fall in the fœtal mortality when cæsarean section increased, but he was working in conditions quite different from those of the United Kingdom today. Broadly speaking, the higher the cæsarean-section rate the lower should be the perinatal mortality, provided the patients are being carefully selected and properly treated before operation. Qureshi's series demonstrates the importance of this proviso, for he is forced to deal with patients who have been examined vaginally before admission (table I) or have been admitted *in irreversible* shock.

Lower-segment cæsarean section is the operation now most frequently performed, but I do not think that the abdomen should be opened with the preconceived idea of invariably carrying out this type of operation. Circumstances may make it difficult—for example:

1. *A poorly developed lower uterine segment.*—This is unusual, but it is very obvious when the abdomen is opened, because all the available lower segment is behind the symphysis pubis, making its exposure difficult. If one persists in trying to perform the lower-segment operation, the lives of both mother and child may be jeopardised. It takes a relatively long time, and almost inevitably the large vessels on either side will be cut or torn.

2. *Adhesions obliterating the operation site.*—This state of affairs is, of course, unlikely unless the patient has had a previous cæsarean section or a low anterior myomectomy.

3. *Marked vascularity of the lower uterine segment.*—This is commonly regarded as an indication for the classical operation, but it need not rule out the segment procedure if the lower uterine segment is well developed and the operator is experienced. Vascularity of the lower segment is common, especially when the placenta is situated anteriorly, and it is an indication for rapid enlargement of the incision in the lower segment, with rapid but careful extraction of the baby.

There are few occasions on which the classical operation has to be performed, and from the point of view of future pregnancies this is fortunate. On the other hand, one must be ready to perform it whenever necessary.

Cæsarean section is desirable in most cases where there is a major degree of placenta prævia, even when the period of gestation is still under 36 weeks. With modern pædiatric care a very large proportion of premature babies can be saved.

The situation of the umbilical cord in relation to the internal os can be of vital importance. Very often the cord is situated excentrically, and usually this does not matter much, because its excentric insertion is far away from the internal os. But where the insertion is just inside the internal os, cæsarean section may be the only means of delivering a live child. The importance of this is evident from the fact that in the first Belfast series (table III) at least 9 of the 33 deaths in babies were directly due to malposition of the cord.

The relation of the cord to the anterior part of the lower uterine segment is also important at a cæsarean section. If it is anterior there is a risk that the cord, or one of the big vessels close to it, may be divided, resulting in the delivery of an anæmic baby. An incision into placental tissue is another indication for rapid delivery of the fœtus.

While cæsarean section has undoubtedly improved the results for both mother and baby, it can have complications necessitating quick decisions and perhaps radical surgery.

Occasionally there is persistent, apparently uncontrollable, hæmorrhage from the lower uterine segment. This may follow the removal of the placenta while the abdomen is still open, and a decision must be made as to whether a hysterectomy is necessary or not. In a multigravida it may be the safest method of treatment, but in a primigravida it will almost certainly be unnecessary. Replacement of blood-loss, and packing the upper and lower segments with gauze (which later can be removed per vaginam), may be all that is required. When bleeding follows closure of the abdomen, it can usually be controlled by the same method, but the intrauterine pack must fill the whole uterine cavity, and ergometrine must be given to make the uterus contract on it.

Placenta accreta is a complication that may have to be faced as soon as the uterus is opened, especially if the placenta is attached to the anterior part of the lower uterine segment. On incising the placenta one sees no line of demarcation between it and the uterine wall, and at this stage there is actually less bleeding than if the implantation was normal. This complication, in association with placenta prævia, is rare, but " in most reported cases of placenta accreta there is a high incidence of implantation of part or all of the placenta in the lower segment " (Millar 1959).

The abnormal adhesion may involve the whole placenta or only the portion attached to the lower segment. Where the whole placenta is involved, or where the condition is one of percreta, hysterectomy has to be performed. Attempts to separate the abnormally adherent placenta are associated with a high mortality from shock and hæmorrhage.

Apparently, a small localised area of placenta accreta can be left with safety, and I have done this on one occasion without untoward result. Kaltreider (1945) quotes 7 cases where the whole placenta was left in situ and all recovered, and Schumann (1940) described 4 cases successfully treated, in the same way, in 2 of which a normal pregnancy followed. Millar (1959) has left the accreta portion in the lower segment in a primigravida of 19 without subsequent complications.

In 1954–58 two women died in the Royal Maternity Hospital, Belfast, from shock and hæmorrhage after cæsarean section.

One was a 9-gravida with a placenta accreta; too much time was spent in trying to remove it manually, and hysterectomy was undertaken too late. The other, a 3-gravida who had had two previous cæsarean sections, was admitted at 26 weeks with a threatened miscarriage. At 34 weeks bleeding was profuse and a classical cæsarean section was performed. This was uneventful, but two and a half hours later she collapsed with uterine bleeding and died.

In the first case a hysterectomy at an earlier stage would almost certainly have saved the patient. In the second case the collapse may have been due to unrecognised postoperative uterine relaxation and intra-uterine bleeding. It emphasises the importance of careful postoperative supervision.

Rupture of the Membranes

Though 60–70% of cases of placenta prævia are now delivered by cæsarean section, artificial rupture of the membranes has still an important place in the treatment of the less severe varieties. The fact that such a large proportion of cases is delivered by cæsarean section suggests that the lesser degrees of placenta prævia are uncommon. But in point of fact many cases of the first degree escape diagnosis because they never have any antepartum hæmorrhage, or nothing more than an excessive show during labour. On the other hand, some minor degrees can bleed quite profusely, and many unnecessary sections will be performed if one makes the mistake of doing cæsarean sections without preliminary vaginal examination.

Where the presenting part can be felt through all the fornices, and the placental edge is reached only after introducing the finger into the lower uterine segment, artificial rupture of the membranes will almost certainly suffice. If the placenta is lying in the second-degree position anteriorly, rupture of the membranes is again likely to be successful. If the placenta is lying posteriorly and the presenting part can be pushed into the pelvic brim without disturbing the fœtal heart, rupture of the membranes is probably the correct treatment in a multipara. If, on the other hand, pressing the fœtal head into the pelvic brim disturbs the fœtal heart, the umbilical cord is almost certainly situated excentrically in close proximity to the lower edge of a second-degree placenta prævia and near the internal os. In such a case rupture of the membranes may result in prolapse of the cord or compression of the cord by the fœtal head, which forces one to perform a rapid cæsarean section in unfavourable circumstances or perhaps be faced with an intrauterine death before the operation can be performed. In addition, the posteriorly situated placenta is more liable to prevent engagement of the head, and persistent bleeding may result from the failure of the fœtal head to compress the separated placenta.

Version

The virtual abandonment of bipolar version has been another important factor in reducing the perinatal mortality, and also, to some extent, the maternal mortality.

This operation has a fœtal mortality of between 60–80% and is now reserved for a few selected cases. It has a definite place where the baby is very immature or already dead, and it is occasionally indicated in the multipara who has a good obstetric history and is in labour with hæmorrhage of such a degree that it must be controlled before any further steps can be taken. Here the baby may be alive, and may even be born alive if the version is carefully and gently performed, and the placenta prævia is of a moderate or minor degree

It has been suggested that in these cases a preliminary external version facilitates extraction of the foot and reduces the amount of internal manipulation required This is true provided the legs are not extended If they are, it will actually increase the internal manipulation and make the extraction of the foot more difficult

Apart from the type of case I have mentioned, podalic version now has a very small place in the treatment of placenta prævia in the United Kingdom and most of the Western world

Criticisms

When I visited the Rhodesias and South Africa as Sims Black professor, I was criticised for my attitude towards the treatment of placenta prævia, and especially for what I said on expectant treatment and cæsarean section I was told that I had oversimplified the subject and that some of my teaching was not applicable to the African patient—indeed was unwise In view of what I saw and heard on my visit I believe that some of these criticisms are sound

I still maintain that the modern treatment of placenta prævia has justified itself, but it depends on hospital and medical facilities which many communities in many countries do not yet possess I have not visited India, but Dr Qureshi's paper criticises expectant treatment in a way that demands attention, and expresses opinions which would be valid in South Africa and possibly some Far Eastern countries He says

> " The present day emphasis on expectant treatment by several authorities notably Macafee (1945), Williamson and Greeley (1945) Johnson (1945) and others and the remarkable reduction in the fœtal mortality reported by them, is likely to excite the enthusiasm of many obstetricians for this method of treatment But every obstetrician must be alive to the environment in which he is practising and the type of patients he is to treat
>
> " There are very few hospitals in this sub-continent which are well equipped, well staffed and highly organised Even if there were a profusion of well-organised institutions, the type of patients we get should not be lost sight of From my experience of six years at the Lady Willingdon Hospital, Lahore, and Victoria Jubilee Hospital, Amritsar, with obstetric patients, I can state without fear of contradiction that our patients are extremely gullible and lend themselves easily to vaginal examination by dais Even they make their own vaginal examinations One of the patients in the present series undergoing expectant treatment in hospital did her own vaginal examination!
>
> " Many of them when admitted to hospital are very co-operative, and ready to accept all conditions for treatment But later on they get weary All of a sudden, as if possessed by a demon, they leave the hospital at their own risk They become completely impervious to otherwise convincing reasoning No amount of persuasion or vivid presentation of frightful consequences can deviate them from their irrevocable decision to leave the hospital This applies to all types of cases, whatever their status The two cases in which death occurred on readmission were private cases!
>
> " In view of these facts, I am of opinion that very serious thought must be given to the prevalent conditions before deciding upon expectant treatment of placenta prævia At present it should be exception rather than the rule When an adequate number of well organised institutions comes into being and the patients are delivered from the clutches of ignorant but all powerful dais and they become, through proper education, more susceptible to rational suggestion for treatment and more consistent in their behaviour, then and then alone can the expectant treatment be instituted on a more extensive scale, with perfect safety to the mother "

In South Africa the frequent use of cæsarean section was also criticised not only because facilities for the operation may be inadequate but also because of the risk of ruptured uterus at subsequent confinement and because of the very high infant mortality

It was pointed out to me that, before leaving a scar in the uterus of a Bantu patient, one must consider her possible subsequent history Her next baby may be born in the kraal with no expert medical or nursing care and the uterus may rupture and the patient die In Rhodesia I myself had to operate on a woman who had ruptured a cæsarean-section scar in the Bush two days before admission to hospital

The infant mortality is relevant because operation on the mother in order to save the child may seem less imperative when the child's prospects of later survival are so much less than they are here In Port Elizabeth in South Africa the annual report of the Medical Officer of Health shows that in 1955 the mortality per 1000 in the first year of life was

European	35 87
Eurafrican	135 6
Asiatic	32 26
Bantu (city only)	356 00
All non-Europeans	218 69

From an ethical standpoint this argument is difficult to defend, but with perhaps one child in three dying before the age of 12 months, more weight attaches to the risk of the mother dying of ruptured uterus at a subsequent confinement

Qureshi feels that in the environment in which he has to work some of the older methods of treatment should be retained he would advocate the use of podalic version almost as frequently as it was used in this country before 1945, and, despite Prof F J Browne's condemnation of them some years ago, he regards Willett's forceps as valuable Indeed he uses them even in relatively major degrees of placenta prævia, whether the presentation is a vertex or breech

Though I rarely use Willett's forceps I believe they occasionally have a place where the placenta is anterior and where some bleeding persists after artificial rupture of the membranes Gentle traction not only controls the bleeding but stimulates uterine contractions, with the result that the forceps have only to be applied for a short time But I would not agree with their use in a breech If the baby is alive, extraction of a foot is the safer and more rational method of treatment if it is dead, version is safer and more effective

It is important for us in the United Kingdom to remember that our situation is exceptional in that hospitals, blood-transfusion, and experienced medical and nursing care are never very far from any patient Elsewhere the distances are often great, the patient is more often ignorant, and the doctors are more likely to lack specialised experience Only by taking this into account can we appreciate the importance of environmental factors in deciding how to treat a case of placenta prævia

I would like to thank Miss Roma Chamberlain, of the *Ministry of Health*, London, for supplying me with data

THE CARPAL-TUNNEL SYNDROME IN PREGNANCY

MARCIA WILKINSON
D.M. Oxon., M.R.C.P.
NEUROLOGIST TO THE ELIZABETH GARRETT ANDERSON HOSPITAL, LONDON, N.W.1, AND ST. MARGARET'S HOSPITAL, EPPING, AND PHYSICIAN TO THE SOUTH LONDON HOSPITAL

PAIN and tingling in the arms and hands during pregnancy are fairly common symptoms, but relatively little attention has been drawn to them as they often do not arise until the last 3 months of pregnancy, and they tend to improve after delivery. In a few cases, however, the patient is in constant pain during the day and is unable to sleep at night.

This series comprises fourteen patients, all of whom were seen during pregnancy, and all but two also after delivery. Seven had compression of the median nerve only. The other seven had signs of median-nerve compression combined with signs of compression of one or more cervical nerve-roots, suggesting a common pathogenesis. One other patient with signs of bilateral median-nerve compression, seen when she was 74, gave a history of numbness and tingling in her hands for 38 years, the symptoms having started when she was 6 months pregnant with her second child.

Acroparæsthesiæ in pregnancy have been described by Walshe (1945), Garland et al. (1957), and Heathfield (1957), amongst others. Various theories have been put forward to explain compression of the median nerve during pregnancy. Guly (1959) and others believe that salt and water retention is the most important mechanism. Hence diuretics have been given by mouth in treatment with some success (McCallum 1959, Wood 1959). Injection of hydrocortisone 0·5–1·0 ml. into the carpal tunnel may also give dramatic relief in a high proportion of cases, including those associated with pregnancy (Philip 1959).

Ætiology

The main ætiological factors in compression of the median nerve in the carpal tunnel during pregnancy are trauma, a rapid or unusually great increase in weight, and, perhaps, changes in fluid content or tension of the ligaments. But relaxation of the carpal ligament can only be important if it causes the relation of the structures in the carpal tunnel to be changed. Pre-existing cervical spondylosis seems to play a part in the syndrome, possibly by partially damaging nerves so that further pressure causes symptoms.

Trauma

It has been recognised for some time that trauma may produce the symptoms of compression of the median nerve in the carpal tunnel (Brain, Wright, and Wilkinson 1947), and any occupation involving forcible dorsiflexion of the wrist may precipitate them. Many household jobs come under this heading. Three patients started to get symptoms when they gave up a sedentary office job and started doing housework, in one shortly after cleaning a large carpet, and in another after interior decorating. In another the symptoms appeared very early in pregnancy (the 13th week), 5 weeks after she had taken a job which involved lifting heavy laundry baskets. Seven patients gave a history of trauma just before the onset of their symptoms.

Weight Increase

Chesley (1944) estimated that the average woman gains 24 lb. during pregnancy—that is an average increase of 24% of the prepregnancy weight. Two-thirds of all pregnant women gain 13–35 lb., one-sixth more than 35 lb., and one-sixth less than 13 lb. The average gain in weight during the first 3 months of pregnancy is not more than 3 lb., but during the 2nd and 3rd trimesters the gain averages 1 lb. per week until shortly before labour, when up to 3 lb. may be quickly lost. The loss continues postpartum, but afterwards there is a net gain of 6 lb. Five patients in this series gained 30 lb. or more in weight during their pregnancy. One patient gained 60 lb. during her second pregnancy. During her first pregnancy the gain in weight had not been excessive, and she did not have symptoms in her hands. In the second pregnancy paræsthesiæ came on early, affecting her right hand in the 19th week, by which time she had already gained 27 lb. Paræsthesiæ did not affect her left hand until the 33rd week. In four other patients there was marked increase in weight, in three paræsthesiæ developed within 4 weeks of a rapid gain in weight, the average increase being 10 lb. in 4 weeks.

Relaxin

Hisaw (1926) postulated a hormone, relaxin, which had a specific effect on the relaxation of the symphysis pubis in the guineapig. Sands (1958) showed that this hormone modifies the pelvic joints in pregnancy, and Sands and Stone (1959) showed that relaxin is a protein or polypeptide soluble in water and highly stable. It has been demonstrated in the blood of pregnant women, increasing in concentration until the 38th week, and disappearing rapidly within 24 hours of parturition. Boucek (1955), using a sponge-biopsy technique, studied the histochemical characteristics of connective tissue in different age-groups. He showed that when the host was treated with relaxin the collagen-fibres became finer and more widely separated, the ground substance was depolymerised, the mast-cells increased in number, and more fluid was imbibed.

The increase in fluid intake may be important in producing the symptoms of median-nerve compression in pregnancy, as it would increase the volume of the contents of the carpal tunnel. Since all ligaments tend to relax during pregnancy, it is reasonable to suppose that those of the carpal tunnel are involved, and that alteration of the stresses and strains at the wrist may play some part in the production of symptoms.

Other Factors

Posture during sleep may be important. Four patients were more comfortable sleeping on their backs during the last few weeks of pregnancy, and five found that the paræsthesiæ were worse if they slept on the affected side. During the day fluid tends to accumulate in the legs, but this tendency is reversed at night when the patient lies flat. This redistribution of fluid may play some part as the symptoms were always worse at night or on waking, even when they persisted through the day. Because radiographic changes were not very conspicuous in the cervical spine, the factors discussed above may have contributed to the radicular symptoms when these were present.

Clinical Features

Symptomatology

All the patients in this series complained of numbnesss, tingling, or pain in the fingers of one or both hands.

In the majority the numbness was in the thumb, index, and middle fingers, or in the index and middle fingers. In one the index, middle, and ring fingers were affected, and in another the ring and little fingers were worse although all the fingers were affected. Twelve of the patients were right-handed, and in all but two the symptoms started in the dominant hand. In nine one hand only was affected, and in the other five both hands were involved. Where both hands were involved the dominant hand was affected earlier in three and the symptoms came on in the opposite hand 1, 9, and 14 weeks later. In two cases both hands were involved simultaneously.

Pain in the neck and shoulder was experienced in two cases, and pain in the wrist and forearm in five.

Seven patients had objective swelling or feelings of tenseness of the hands; in one swelling was so severe that she had to have her wedding ring cut off. No patient in this series had toxæmia of pregnancy. Backache was not common, occurring in only four patients.

Of the seven patients with symptoms due to a combination of median-nerve and cervical-root pressure four showed flattening and one showed exaggeration of the normal cervical curve. The seven patients with median-nerve compression only were slightly younger than those with both nerve and root compression (26·7 years compared with 29·7 years). In five cases the symptoms appeared during the first pregnancy.

None of the patients had had symptoms for long. The average time for the whole group was 10·1 weeks, for those with median-nerve compression only it was 7·9 weeks, and for the mixed group 12·4 weeks. The symptoms usually improved after delivery; in four patients they disappeared within 48 hours but in most residual symptoms persisted for 1–4 weeks. One patient improved while she was resting in bed for 2 weeks before delivery. In two the symptoms persisted. One of these required decompression of the median nerve 10 months after delivery; this was the only patient needing operation. The other patient who did not improve continued to have pain in her arms, and radiographs 9 months later showed the characteristic changes of cervical spondylosis.

Physical Signs

Impairment of awareness of pinprick or cotton-wool in the distribution of the median nerve was the most common sign, being found in eleven of the fourteen patients. Only three showed wasting and weakness of the thenar muscles. Reflex changes were found in five patients who had compression of the median nerve and of one or more cervical nerve-roots; one or both triceps jerks were diminished in four, and the biceps jerks in one. Movement of the cervical spine was limited in three patients, and in three there was drooping of one shoulder. One patient who was heavily built had a short thick neck with a marked upper dorsal kyphosis.

Radiological Changes

The cervical spine was X-rayed in twelve cases. Eight showed slight loss of the normal curve, four had diminution of one or more disc spaces, and two showed narrowing of the intervertebral foramina. Since none of the patients gave a history of injury to their wrists these were not X-rayed routinely.

Treatment

Because the symptoms were usually worse at night or in the early morning sleeplessness was one of the main complaints. Hence a sedative such as amylobarbitone sodium was given, together with an analgesic. Patients were advised not to lie on the affected arm, as this tended to make the symptoms worse. In most cases this was the only treatment required.

Splinting was sometimes helpful, being used for three patients; one improved a good deal, another improved slightly, and the third was unchanged. A light splint, applied to the dorsal surface of the wrist, was bandaged around the palm and forearm, the wrist being kept in the neutral or slightly flexed position. The palmar surface of the wrist should never be splinted as this tends to increase the pressure on the median nerve, making the symptoms worse.

During pregnancy the symptoms are rarely sufficiently severe to require immediate operation, and, as they tend to improve spontaneously during the puerperium, operation should be delayed until after delivery. Symptoms persisted after delivery in only one patient in this series; she was operated on several months later, with relief.

Where the symptoms were due to compression of the median nerve and cervical nerve-roots sedation was combined with active exercises for the neck and shoulders. Seven patients were so treated, with some improvement in four.

Summary

In fourteen patients symptoms due to compression of the median nerve in the carpal tunnel appeared during pregnancy. Seven also had symptoms of cervical radicular lesions.

Trauma may precipitate the median-nerve compression in some cases, but the metabolic changes, and especially fluid retention, associated with pregnancy appear to be the main causal factor.

The immediate treatment is symptomatic. Since most patients recover spontaneously after delivery, operation should be deferred and is then rarely necessary.

My thanks are due to Sir Russell Brain for his help and advice, and to Miss M. H. Calverley, Miss W. P. Lewington, and Miss J. A. M. Moore for referring patients to me.

HYDROCORTISONE AND THE CARPAL-TUNNEL SYNDROME

JOHN B. FOSTER*
M.B. Durh., M.R.C.P.

LATE REGISTRAR TO THE DEPARTMENT OF MEDICINE,
KING'S COLLEGE, UNIVERSITY OF DURHAM

THE commonest cause of acroparæsthesiæ limited to the distribution of the median nerve in the hand is now widely accepted as compression of the median nerve in the carpal tunnel. Since the initial description by Brain et al. (1947) of symptomatic relief by simple retinacular section many reviews of the pathogenesis of the syndrome and its surgical treatment have appeared (Woltman 1941, Nissen 1952, Kremer et al. 1953, Grokoest and Demartini 1954, Garland et al. 1957, Heathfield 1957, Phalen and Kendrick 1957, Vainio 1957, Dick and Zadik 1958, Wiley 1959).

Acroparæsthesiæ in the median-nerve distribution may occasionally arise in the course of systemic disease, such as rheumatoid arthritis, myelomatosis, or amyloidosis (Grokoest and Demartini 1954, Keith 1957). The syndrome not infrequently follows fractures at the wrist, and it may be associated with ganglia of tendon sheaths or with capsular thickening of rheumatoid disease of the wrist-joint itself. But most cases arise in middle-aged women without general disease or local lesion at the wrist.

If compression of the median nerve is secondary to non-specific thickening of the tendon sheaths entering the carpal tunnel, then the nocturnal exacerbations which are so constant a feature may well be due to the increase in bulk of this enclosed tissue by the generalised vaso-

* + = some improvement, − − = great improvement, − = no improvement, c = symptom-free, r = recurrence of symptoms

dilatation of deep sleep The constant trauma provoked by flexion-extension movements at the wrists has been invoked as the cause of the more persistent symptoms on which these characteristic exacerbations are superimposed

Non-specific inflammatory swelling of soft tissues responds well to the injection of hydrocortisone. Hence, drawing a loose analogy between the tenosynovial swelling of the flexor tendons in and above the carpal tunnel and the synovial thickening of the rheumatoid joint, I decided to observe the effect of hydrocortisone instilled into the carpal tunnels of a series of patients with median-nerve acroparæsthesiæ, as suggested by Phalen and Kendrick (1957)

Investigation

The Patients

Twenty patients were referred from the outpatient department of a general hospital for treatment (see table)

All fulfilled the criteria of pain or paræsthesiæ in the median-nerve distribution of the hand for more than 6 weeks, aggravated by exercise at the wrist, and with nocturnal exacerbations Some had unrelated systemic disorders as shown in the table. Sensation (light touch, pinprick, and two-point discrimination) was examined in all cases, and the muscles supplied by the median nerve were tested for power, particular attention being paid to the strength of the abductor pollicis brevis Radiographs of the cervical spine were taken in each case to exclude " cervical rib "

Technique

Hydrocortisone tertiary butyl acetate (Merck) 1 ml (25 mg) was injected into the volar aspect of the wrist at the junction of the medial edge of the palmaris-longus tendon and the proximal border of the retinaculum. Three injections were given into each wrist at weekly intervals, and the symptoms and signs were reviewed each week thereafter

The skin was prepared with spirit and iodine. A ' Star ' 20 needle (1 5 cm. long) was used, being introduced to maximum depth at an angle of 45° to the surface of the arm in its longitudinal axis (Injection of the wrists of cadavers with coloured solution confirms that the substance comes to lie deep in the tunnel, so that on movement it will circulate amongst the tendons below the retinaculum, coming into contact with the nerve itself on its deep aspect.) Patients were encouraged to use the hand after injection and not to restrict their activity

Results

The progress of each case is shown in the table. Of the twenty patients, one wrist only was affected in fifteen. Of these, ten had become symptom-free 3 to 8 months after the third injection of hydrocortisone. Of the other five patients in whom both wrists were involved, eight wrists became similarly symptom-free Three of the remaining seven wrists improved so much that the symptoms became tolerable and the patients did not wish to have further treatment In two others the symptoms recurred after a period of improvement, and the remaining patients who had in no way benefited by injection, were referred for operation

Thus twenty-five carpal tunnels were injected with complete relief of symptoms in twenty, partial relief in three, and no improvement in two Assessment after 12 months, however, showed a high relapse-rate in those who had initially improved, symptoms recurring in fourteen wrists Of the original twenty who obtained complete relief only six were symptom-free after 12–14 months, and five more needed surgical treatment

Discussion

Most patients who responded did so after the first injection. Many experienced an exacerbation of symptoms during the 24 hours after injection, which was never prolonged. But in view of this the injection of more than 1 ml of fluid into an already tightly packed compartment is probably unwise. Only seven cases showed objective signs of median-nerve damage—namely, clinically detectable sensory loss and thenar atrophy—and these signs had not improved at the time of intermediate follow-up (see table)

This investigation suggests that hydrocortisone injected into the carpal tunnel by the above technique will give temporary relief of acroparæsthesiæ in many cases without evidence of severe median-nerve damage, and more permanent relief in a few A larger group of patients is now being studied to discover whether nerve conduction-time is improved by the procedure, which provides a relatively painless and economical alternative to surgical treatment

Summary

Hydrocortisone was injected into twenty-five carpal tunnels of patients with median-nerve compression

The symptoms remitted completely in twenty cases, three derived some benefit, and two did not improve

This form of treatment, which is simple, relatively painless, and economical, may be preferable to operation in early cases without evidence of severe median-nerve damage, or with some contraindication to surgical treatment Unfortunately the relapse-rate is high

A HITHERTO UNDESCRIBED PHENOMENON IN ABO HÆMOLYTIC DISEASE OF THE NEWBORN

S Lewi
M D Paris

T K Clarke
RESEARCH ASSISTANT

From the National Blood Transfusion Centre, Paris, France

The serological diagnosis of ABO hæmolytic disease of the newborn is sometimes very difficult The Coombs test is generally negative or very weakly positive, and the titre or nature of the maternal antibodies bears no clear-cut relationship to the severity of the baby's affection For early diagnosis many tests involving examination of the cord blood have been suggested, none is reliable, and close observation of all newborn children and measurement of indirect-reacting serum-bilirubin whenever early or deep jaundice exists, are the only sound guides to diagnosis and treatment (Tovey et al 1959)

The aim of the present paper is not to add a further test but to describe a phenomenon which until now does not seem to have been observed Erythrocytes suspended in an agglutinating serum sediment more quickly than those suspended in a compatible serum (Sander and Sander 1939, Stats 1950) We have shown that the hastening of the sedimentation is conditioned by, among other factors, the intensity of the agglutination, the packed-cell volume of the preparation, and the nature of the medium in which the agglutinated cells are suspended (Lewi 1954) We therefore decided to investigate the behaviour in this respect of erythrocytes from infants with hæmolytic disease Obviously, the erythrocyte-sedimentation rate (E S R) of whole cord blood cannot have any significance for this purpose, the E S R of cord blood is always very low (much lower than that of normal adult blood) owing to the composition of newborn's plasma (poor in α and β globulins and in fibrinogen) and to the high hæmatocrit level, whereas the tendency towards rouleaux-formation is the same in fœtal and in adult cells (Lewi 1955) Thus, for study of the action of antibody fixation on the red corpuscles of the baby, it is necessary to compare samples containing erythrocytes entirely free of plasma, suspended in a constant medium under a constant concentration

Material and Methods

Unclotted cord-blood samples were obtained on heparin (0 1 mg of pure heparin per ml. of blood) The blood was centrifuged, the plasma removed, and the cells washed three times in neutral-phosphate-buffered isotonic saline solution The red cells, as completely packed as possible, were mixed with polyvinyl-pyrrolidone (P V P) medium, and prepared as described later, in the proportion of 1 vol of packed cells to 3 vol of P V P medium The tubes were shaken gently and sedimentation was carried out in a Westergren tube (200 mm high, 3 mm internal diameter) Readings were taken every 5 minutes The 10 min and 15 min readings are of the most interest

The P V P medium was made up by diluting 25% concentrated P V P (' Subtosan retard ', Specia) in normal isotonic saline The dilution was chosen in such manner that a 1 3 (v/v) suspension of fresh cord erythrocytes, washed and packed as above, of normal ABO-compatible full-term infants showed an average E S R of 5 mm in 10 minutes The final dilution of P V P giving such a result varied widely between different batches, and may range between 1% and 2 4% Once the dilution has been determined, the same batch may be used for several hundred tests

Many hæmatological and immunological tests were performed simultaneously on the cord-blood samples they will not be described here

Mother's blood for titration of incompatible anti-A or anti-B antibodies was obtained generally on the day of delivery, but sometimes 1 or 2 days afterwards Titration was made on A_1 or B adult red cells (1) in saline at room temperature and (2) in human AB serum at 37°C, hæmolysins, if present, were titrated in inactivated serum to which fresh human group-O serum known to contain no hæmolysins had been added

The newborn children were looked after by the hospital pædiatrician When necessary, hæmatological examinations and indirect-reacting bilirubin measurements in the baby's serum served as a guide for treatment, independently of our laboratory findings The policy was to perform an exchange-transfusion with group-O blood when the indirect bilirubin reached 20 mg per 100 ml , and a simple transfusion of packed cells when the red-cell count dropped below 3×10^6 per c mm Most of the children with deep jaundice, compatible or incompatible, received cortisone treatment (10-20 mg of Δ-cortisone by mouth daily for 3 or 4 days)

Results

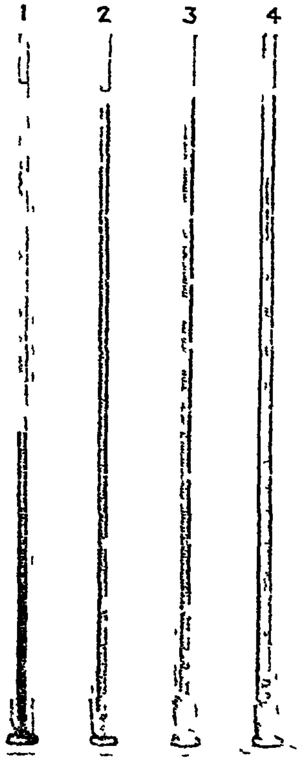
Of 3924 cord-blood samples, 835 were incompatible in the ABO system with the mother's group (Children affected by Rh-hæmolytic disease, stillbirths, and children who died or left the clinic less than 3 days after birth are not counted) The distribution of incompatible children was as follows

Mother O, child A	416 cases
Mother O, child B	147 „
Mother A, child B or AB	146 „
Mother B, child A or AB	126 „

The sedimentation of *compatible* cord red cells in P V P medium conformed to a rhythm which was the same in all blood samples examined the fall of 5 mm in 10 minutes, chosen as an arbitrary reference, continued at the rate of 5 mm every 5 minutes, and packing was not complete after $1^1/_2$-2 hours The same sedimentation rate was observed in compatible blood of premature children and those with obstetric complications, and even those who died a short time before labour or during labour.

The sedimentation of *incompatible* cord red cells, on the other hand, varied greatly from one sample to another, and striking differences were seen most easily by simultaneous observation of a series of tubes. Between a normal range and a much-hastened sedimentation-rate there was a whole range of intermediate rates which by means of the 10-min. and 15-min. readings could be divided into three categories.

1. *Greatly accelerated sedimentation.*—The fall of the red cells was most dramatic. After 10 minutes the column of clear supernatant fluid amounted to 90 mm. or more. The erythrocytes packed at the bottom of the tube were clearly delineated from the supernatant liquid, in which only a few unagglomerated cells persisted. 10-minute readings of blood from group-A children of group-O mothers are shown in the accompanying figure.



Sedimentation of four samples of cord-blood erythrocytes in P.V.P. medium after 10 minutes. Tube 1, child with ABO hæmolytic disease (case C, table I); tubes 2–4, healthy group-A children of group-O mothers.

Tube 1 contained the blood of an infant with hæmolytic disease (case C, table I) and it contrasts sharply with tubes 2–4, containing blood of healthy infants.

Such a much-accelerated sedimentation-rate has been found in only 8 out of 835 incompatible cord bloods; all 8 were of mother O/child A.

2. *Moderately accelerated sedimentation.*—The 10-min. readings did not show a clear delineation between the packed cells and those remaining in suspension. The supernatant liquid became transparent gradually, the density of the red cells increased progressively from top to bottom, and at the lower extremity of the supernatant fluid small clusters of agglomerated erythrocytes could be seen distinctly with the aid of a lens. In contrast, the 15-min. reading showed a massive red-cell deposit separated from the supernatant by a neat line of demarcation.

Such a type of sedimentation was found in 25 out of 835 incompatible cord bloods—23 times in the combination of mother O/child A, and twice in the combination of mother O/child B.

3. *Normal or slightly accelerated sedimentation.*—In this category we have included all cases in which the 15-min. readings showed no important sedimentation, such as a compact layer of red cells separated by a neat demarcation line at least 85 mm. below the upper limit of the tube.

In many cases incompatible cord red cells did not settle more quickly than compatible ones. In compatible ABO children affected by Rh hæmolytic disease the sedimentation of cord erythrocytes in P.V.P. medium was not distinctly modified: out of 20 cases we found 17 normal sedimentation-rates, and in the other 3 cases the sedimentation-rate was very slightly accelerated (20 mm. at 15-min. readings instead of 10 mm. as in normal ABO compatible children).

In each of the 8 cases where the cord-E.S.R. in P.V.P. was strongly increased the child had severe hæmolytic disease: 4 of them showed both early anæmia and high indirect bilirubin levels, and underwent exchange-transfusions. In 1 case anæmia (Hb 11·5 g. per 100 ml.) and hyperbilirubinæmia (17 mg. per 100 ml.) existed in a child 5 days old, at which age the infant left the clinic with its mother, who refused treatment. In 2 cases the indirect bilirubin never reached a dangerous level, but the children had to be transfused with group-O packed

TABLE I—DATA CONCERNING 8 CHILDREN WITH GREATLY INCREASED SEDIMENTATION-RATE OF CORD CELLS IN P.V.P. MEDIUM (ALL CHILDREN GROUP A, MOTHERS GROUP O)

Case	Maternal anti-A antibody at delivery			E.S.R. of cord cells in P.V.P. medium (mm.)		Osmotic fragility Hæmolysis *		Clinical condition of infant and treatment	Previous family history
	Saline	Human AB serum 37 C	Hæmolysin	10 min.	15 min.	Initial	Complete		
A	128	1024	4	104	108	0·62	0·42	Full-term, 3·120 kg., early jaundice and anæmia, 2 exchange-transfusions	Primipara
B	128	1024	8	130	132	0·62	0·42	Premature, 7½ months, 2·520 kg., early jaundice and anæmia, 1 exchange-transfusion	8 previous children (group unknown) unaffected (?), 3 miscarriages
C	512	16,000	32	105	118	0·65	0·45	Full-term, 3·460 kg., early jaundice and anæmia, 1 exchange-transfusion, child died at 1 month (cardiac malformation)	2 first children A_1 unaffected, 3rd dead at birth, 4th A_1, exchange-transfusion, 5th A_1 affected and transfused, 1 miscarriage
D	256	4096	4	100	118	0·65	0·38	Full-term, 2·620 kg., early jaundice and anæmia, transfusion of packed cells	Primipara
E	256	512	1	96	100	0·65	0·42	Full-term, 3·560 kg., early jaundice and anæmia, transfusion of packed cells	1st child (group unknown) unaffected, 2nd A_1 early jaundice not treated
F	1024	8192	8	87	92	0·52	0·35	Full-term, 3·500 kg., early jaundice and anæmia, left clinic at 5 days without treatment	Primipara
G	512	2048	2	97	110	0·55	0·35	Full-term, 3·590 kg., early jaundice and anæmia, 1 exchange-transfusion	1st child A_1 unaffected
H	128	512	2	85	110	0·55	0·35	Full-term, 3·880 kg., no jaundice or anæmia until 5th day, late anæmia (1 month) treated by transfusion	1st child group O unaffected

* Normal range with our technique in phosphate buffered saline: initial hæmolysis, 0·50–0·55; complete hæmolysis, 0·30–0·35.

TABLE II—INCIDENCE OF NEONATAL JAUNDICE IN 3924 INFANTS

Blood-groups	Sedimentation of cord red cells in P V P medium	No of cases	No jaundice	Slight jaundice	Deep jaundice	Exchange transfusion
Mother O, child A	Greatly accelerated	8	1	0	7	4 (twice in 1 case, see table I)
	Moderately accelerated	23	4	4	15	1
	Normal or slightly accelerated	385	241	121	23	0
Mother O, child B	Moderately accelerated	2	0	0	2	0
	Normal or slightly accelerated	145	91	44	10	0
Mother A, child B or AB	Normal or slightly accelerated	146	96	42	8	0
Mother B, child A or AB	Normal or slightly accelerated	126	82	37	7	0
Compatible children		3089	2039	886	164	1 (full term infant)
Total		3924	2554	1134	236	6

cells in the first week of life to correct anæmia In 1 case no anæmia or jaundice was observed until the child had left the clinic (5 days), but at the age of a month the child was admitted to a children's hospital with anæmia The data concerning these 8 cases are summarised in table I

In the 25 cases where the sedimentation-rate was moderately increased, the incidence of deep jaundice was very high (17 cases out of 25), and no anæmia was noticed, 16 of the children recovered without special treatment, although in 11 cases the indirect bilirubin reached very high, but not dangerous, levels In 1 case an exchange-transfusion had to be performed at the 4th day on account of hyperbilirubinæmia Of the 8 remaining cases slight jaundice was observed in 4, but serum-bilirubin was not measured

Among all other cases of ABO incompatible infants whose cord-erythrocytes showed a normal or slightly accelerated sedimentation in P V P medium the incidence of deep jaundice was not significantly greater than in the control group of ABO compatible children (table II) In this last group, 1 full-term infant had to undergo an exchange-transfusion on account of hyperbilirubinæmia of undetermined origin

Discussion

The phenomenon described here is the outcome of several years' research concerning ABO hæmolytic disease of the newborn and, principally, the means of early diagnosis We have studied most of the tests evolved for this purpose, all have been found disappointing In our experience, the hæmatological anomalies—i e, anæmia, high reticulocytosis, microspherocytosis, and increased osmotic fragility of the cord-erythrocytes—are very frequently absent in affected children By contrast, immunological tests are very often positive in perfectly healthy infants, especially in group A or B infants whose O mothers have a high-titred incompatible antibody Rosenfield's (1955) modified Coombs' test and the agglutination of cord-erythrocytes in macromolecular media is so often positive (sometimes quite strongly) in infants without jaundice that these tests cannot be taken into practical account Moreover, in healthy infants the presence of incompatible maternal antibody free in the cord serum *and* attached to the cord-erythrocytes, which give it up by elution, is sometimes observed, thus proving that the passage of incompatible antibody across the placenta and even its fixation on the child's red cells does not by itself always give rise to hæmolytic disease Something else must occur—perhaps modifications of the cell surface which manifest themselves in the agglutination of the erythrocytes in macromolecular media Such modifications do not seem to be a constant consequence of fixation of antibody on A or B cells The effect of such modifications is generally not deleterious for the red corpuscles, unless they reach a great intensity, and the intensity is not necessarily proportional to the amount of antibody fixed

Unfortunately, this intensity cannot be determined by a slide agglutination test We have tried to measure it by means of the sedimentation-rate, just as the intensity of rouleaux-formation of erythrocytes in their own plasma is measured by this technique The results, reported here, are very promising In all cases where the sedimentation-rate was greatly accelerated the children had severe hæmolytic disease, with anæmia and with or without hyperbilirubinæmia In cases with a moderately increased sedimentation-rate hyperbilirubinæmia was quite common, but this was not associated with anæmia and in our series required no special treatment, except in 1 case, moreover, in certain of these cases no jaundice was observed, so probably the immunological process played only a subsidiary role in the genesis of the disease In the cases where the cord-red-cells' sedimentation-rate was normal or only slightly increased, the incidence of deep jaundice was not significantly greater than in the compatible children In such cases when jaundice occurs the incompatibility plays probably a very small role, if any, whatever the nature and titre of maternal antibody

The phenomenon described here is observed only in hæmolytic disease due to ABO incompatibility The cord-red-cells' sedimentation-rate is normal or only very slightly increased in even severe Rh hæmolytic disease in ABO compatible children, showing that in this disorder the cellular modifications are quite different This difference of behaviour of cord-erythrocytes in ABO and Rh hæmolytic disease was observed by Munk-Andersen (1958) with his dextran/human-serum medium

A more detailed report of our work on ABO hæmolytic disease will appear elsewhere

Summary

The sedimentation-rate of washed cord erythrocytes suspended in a P V P medium was found to be greatly increased in severe ABO hæmolytic disease, and moderately but distinctly increased in most of the less severe cases

This phenomenon may prove useful in the study of cell changes in ABO hæmolytic disease of the newborn

We wish to thank Prof M Mayer and Dr P Walter, obstetricians, Saint-Antoine and Rothschild Hospitals, and Dr P Ducas, pædiatrician, Saint-Antoine Hospital, for their cooperation and interest We are grateful to the midwifery staff at both hospitals—especially to Miss A Dinovetzky for the collection of cord-blood samples

SURGICAL RELIEF OF SEVERE PARALYTIC HIP CONTRACTURE

DAVID ALLBROOK
M.B., Ph.D Lond.

H. FLETCHER LUNN
M.B. Lond. F.R.C.S

From the Departments of Anatomy and Surgery Makerere College Medical School Uganda, East Africa

THIS paper reports favourable results of an attempt to relieve the severely crippling deformity of the hip which follows untreated anterior poliomyelitis in Uganda. The appearance of a child so afflicted suggests the need for extensive surgery involving many operations over a long period. Because most of these cases are in countries where neither hospital beds nor operating facilities suffice for this type of treatment, the children are left alone. They grow up as helpless cripples with the prospect of only a short miserable existence without schooling and without any hope of earning a living except by begging. If the child can be enabled to walk upright he can be sent to school and thus become a useful member of society. The procedure to be described reduces bed-occupancy and operating-time to a minimum and can be followed wherever there is basic medical equipment. Its simplicity will appeal to those in medical charge of isolated hospitals in underdeveloped countries. Its effectiveness may lead to a reappraisal of the need for the major operations which form the orthodox treatment in orthopaedic centres.

A child may be brought for advice because of a limp due to mild flexion deformity of the hip-joint after an attack of anterior poliomyelitis. Full flexion of the contralateral hip-joint eliminates lumbar lordosis and often reveals a greater degree of contracture than was at first expected. More often gross deformity is present (fig 1) and the child is unable to walk but crawls on all fours, or sits crouching in a fixed "tailor's position." The hips are then flexed, externally rotated and abducted, the knees are flexed, and the feet plantar flexed.

Before a child in this condition can be taught to walk upright with crutches and callipers, various problems must be overcome. Deformity at the knee can be corrected by repeated manipulations and plasters. Subcutaneous tenotomy of the tendo Achillis (White 1943, Cummins et al. 1946) will relieve fixed plantar flexion. No equally simple method of relieving flexion contracture at the hip has been found in the literature.

The operation described by Campbell (1923) and since modified in many ways, is a major procedure involving detachment of the glutei from the ilium and open division of all structures anterior to the hip joint. The contracture is effectively overcome but apart from the time taken in the theatre over an extensive dissection there are several disadvantages. Because it is a major procedure it is impracticable for both sides to be treated at the same time in bilateral cases, even if blood-transfusion is available. A full plaster spica is invariably required and the stay in hospital lasts several months while repeated operations are also performed on the knees and ankles. The approach to the hip results in all the muscles around the joint being either detached from their origins or divided, whether they are paralysed or merely contracted. After operation the hip thus tends to become flail and unstable. For this reason greater difficulty has been experienced in training a child to walk after this operation than after the simpler procedure described below.

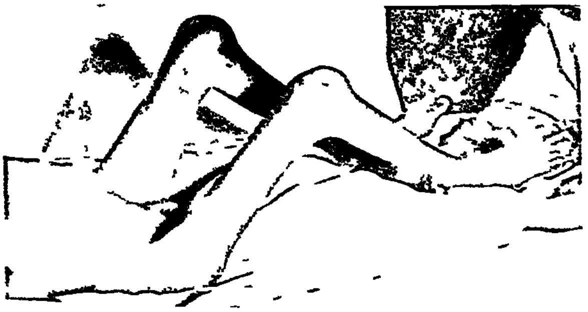

Fig 1—Severe contracture of knees and hips in boy of 9 years, unable to do more than sit at home during past four years.

In February 1958, Mr Robert Roaf demonstrated a method he had developed in India when facing problems similar to our own. The basis of his operation was multiple subcutaneous division of the fascia lata. Successful application of this method depends on an understanding of the factors causing deformity in late poliomyelitis. The following analysis is based upon experience in treating 286 patients with varying types of paralysis of the lower limbs.

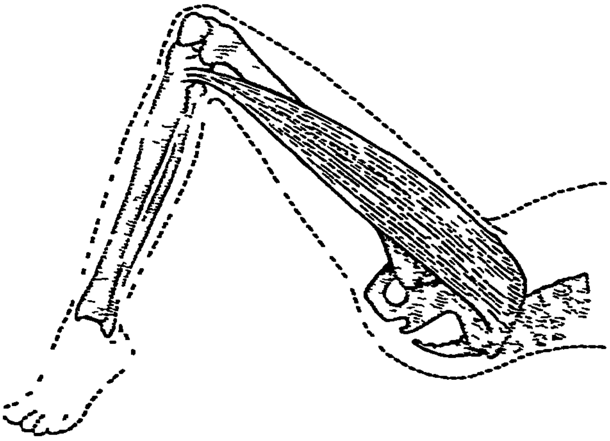

Fig 2—Diagram showing effect of shortened iliotibial tract on knee- and hip-joints.

How Deformity is Produced

The deforming forces are multiple, but may be divided into those which begin to operate soon after the onset of paralysis, and those which later perpetuate the deformity.

The *initial deforming force* is the loss of balance between the paralysed muscles and their antagonists. Thus in the hip region the gluteus maximus and hamstrings are often paralysed whereas the iliopsoas escapes, drawing the thigh up into a flexed position, or there may be loss of adductor power with continued action of the gluteus medius causing abduction. Loss of the glutei together with adoption of the squatting posture will result in external rotation at the hip.

The *later deforming force* results from the propensity of collagen fibres to shorten, taking up the slack between two points of attachment. This force is inherent in the following structures relevant to the hip:

(1) The fascia lata of the iliotibial tract will shorten as its point of attachment on tibia and crest of ilium come closer together. The tract stays as a rigid band and cannot be stretched by any manipulative force alone (fig 2).

(2) Unopposed intact muscles will shorten and may need considerable force applied over a long period to stretch them out to their normal length. Iliopsoas muscle is the most important example of this.

(3) A paralysed muscle may be overstretched, undergoing fibre atrophy and dense interstitial fibrosis.

Roaf's Operation

Underlying Principles

The type of operative correction to be described avoids interference with normal tissues and deals with the deforming forces as follows

(1) The shortened fibres of the iliotibial tract, together with its deep attachments to the femur, are divided at several points along the lateral aspect of the thigh (fig 3) This releases contracted tissues which are strung across at some distance from the flexed hip-joint It also allows the knee-joint to be extended, so that relaxation of the quadriceps extensor permits further correction at the hip

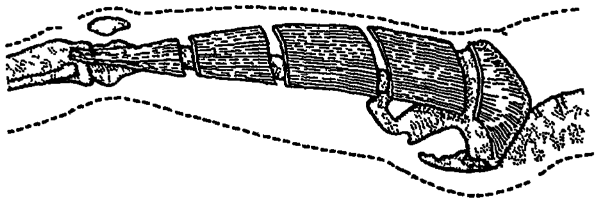

Fig 3—Diagram showing effect of operative division of shortened iliotibial tract

(2) The hip can then be extended by gradually stretching the shortened iliopsoas muscle, and the joint capsule These structures, in intimate contact with the bony surfaces, can later be stretched gradually by leverage upon the femur In most cases, extension exercises alone will suffice after operation In very severe cases stretching under anæsthesia and plaster-spica fixation may be required at intervals of about ten days until full correction is attained

(3) Hip extension allows stretched paralysed muscle (e g, gluteus maximus) to assume normal length, and thus to utilise any surviving motor units This may be the reason for an increase of muscle power which sometimes appears after severe deformity is corrected

Details of Operation

The patient is given a general anæsthetic and the affected hip and knee are extended as fully as possible The opposite hip is flexed to eliminate lumbar lordosis A tenotomy knife is introduced at four or five points along the lateral surface of the thigh, the first proximal to the knee-joint At each of these points the blade is pressed against the tensed fascia lata, then through the underlying fibrous tissue sheaths and septa of the (usually paralysed) vastus lateralis muscle until the bone is reached As these fibrous structures are divided, both the knee and the hip joints can be extended progressively.

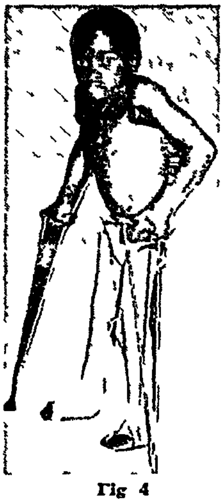

Fig 4

Fig 5

Fig 4—Patient in fig 1 four weeks after operation Hip spica has been removed and correction is almost complete

Fig 5—Same patient at home wearing callipers and now one of the family again

The femoral vessels are then palpated and guarded by a finger A tenotomy incision is made, 1 cm distal to the anterior superior iliac spine The knife is passed medially parallel to the inguinal ligament until the point lies beneath the skin lateral to the femoral sheath The blade is then pressed deeply against the tensed fibres of the fascia lata as they stand out under the skin The origins of sartorius and tensor fasciæ latæ (enclosed within the fascia) are usually divided at the same time, but the knife does not reach as deeply as the capsule of the joint or the tendon of iliopsoas

Bleeding from division of the superficial iliac circumflex artery may be brisk, but can be checked by firm pressure maintained for a few minutes The knife is then withdrawn and reinserted at the same place, the point now directed posteriorly The blade is pressed medially against the remaining fibres of the fascia lata as they pass over the glutei (medius and minimus) The tendons of these glutei are detached from the greater trochanter via a separate incision only if gross abduction deformity is present Minor degrees of abduction deformity at the hip assist in stabilising the pelvis while walking

A plaster cast is applied to the leg as its weight assists in maintaining extension of the hip, and later provides a temporary support for walking exercises When both hips have been treated in this way, the two plaster cylinders are sometimes bridged by a bar of plaster which checks external rotation and prevents the child from lying on his side with the hips flexed The physiotherapist visits daily, and by gentle passive extension of the hip completes the correction of any deformity remaining after the operation The child is nursed throughout either flat on his face or on his back

The most severe degrees of flexion deformity cannot be corrected in this way alone, because of the bowstring effect of the femoral neurovascular bundle across the flexed hip After operation, therefore, the hip is extended as far as the soft tissues allow, and a plaster spica is applied This plaster is either wedged or changed at intervals of ten days, until full correction is achieved (fig 4)

After operation, even in bilateral cases, there is relatively little pain, and some of the younger children are able to start walking by the side of their beds within two or three days In a fully corrected limb, the plaster is removed some fourteen days after operation, and the child is fitted with boots and simple adjustable length callipers (Burkitt 1959)

Results

So far 32 children have had either one or both their hip contractures relieved by this method Over the past eighteen months of continued observation there has been no relapse, although in some instances callipers had been temporarily discarded Once taught to walk, most of the children became determined to remain upright, and they were helped to attend local schools (fig 5) Regular visits were made to their homes to ensure that their boots, callipers, and crutches were maintained in good condition and changed when necessary This service is an essential supplement to the operation

An unexpected result of the operation (performed mainly for deformity of the hip) has been the ease whereby associated flexion contracture at the knee has been relieved None of the 32 patients so far treated have required osteotomy or open capsulotomy of the knee-joint, even though the original deformity has in some instances been over 90° of fixed flexion Division of the fascia lata therefore removes a deforming force which acts on both joints, as shown in figs 2 and 3

Apart from minor local hæmatoma, only 1 of the children treated in this way has suffered postoperative complications A child of 3 years, known to be suffering from sickle-cell anæmia, had a crisis after operation, but later recovered and became ambulant

Conclusions and Summary

The operation of multiple subcutaneous division of the fascia lata has enabled 32 African children with hip contractures to walk.

Major surgery in all these cases has been avoided and interference in the routine of a busy general hospital has been slight.

The operation has been only a phase in the management of each patient. Walking instruction, fitting and maintenance of callipers, and home visiting have also been necessary.

It is hoped that a wider application of this method will enable paralysed children to become ambulant in those countries where they have hitherto been considered beyond the scope of surgical aid.

The procedure we have described offers certain theoretical and practical advantages over the more extensive operations at present accepted as the recognised orthopædic treatment for contracture of the hip.

This investigation has been made possible by the enthusiasm and generosity of the Kampala Round Table, whose members have organised and financed the poliomyelitis clinic at Mulago Hospital.

Our thanks are also due to Prof. I. W. J. McAdam for his guidance and advice, to Mr. Peter Gall for the illustrations, and to Mr. Robert [illegible] for his permission to describe a method which he originated himself.

RECURRENT HEPATIC COMA TREATED BY COLECTOMY AND ILEORECTAL ANASTOMOSIS

MICHAEL ATKINSON
M.D. Lond., M.R.C.P.
LECTURER IN MEDICINE

J. C. GOLIGHER
Ch.M. Edin., F.R.C.S.
PROFESSOR OF SURGERY

UNIVERSITY OF LEEDS

The neuropsychiatric manifestations of liver disease are believed to result from cerebral damage caused by nitrogenous substances formed in the gastrointestinal tract, which normally are removed by the liver and do not enter the general circulation in quantity. Hepatic damage may allow these nitrogenous substances to reach the brain, either by passing through the damaged liver, or by circumventing the liver through portasystemic collateral channels which have developed as a result of portal venous obstruction (Kirk 1956). Portacaval anastomosis, which forms such a shunt, is not infrequently followed by neuropsychiatric disturbances (McDermott and Adams 1954), and Riddell (1955) placed the incidence of this complication as high as 10% after shunt operations.

As the offending substances are formed from ingested protein by bacterial action in the intestine, symptoms are often controlled by restriction of protein in the diet and by antibiotics, such as neomycin, which reduce or modify intestinal bacterial activity. Although usually remarkably effective, this regimen has certain disadvantages. In some patients protein restriction may have to be carried to the point of nutritional impairment, which in turn may lead to hypoproteinæmia with œdema and ascites. Prolonged administration of broad-spectrum antibiotics may cause gastrointestinal disturbance and intercurrent infection with resistant staphylococci or yeasts.

In the case described here these measures failed to prevent recurrent attacks of hepatic coma and led to gradual deterioration of the nutritional state. The problem of reducing intestinal bacterial activity to a minimum was solved by performing colectomy with ileorectal anastomosis, after which no further episodes of stupor or coma occurred and the patient tolerated a normal diet, thus enabling undernutrition to be corrected.

Case-record

A housewife had had recurrent hæmatemeses from the age of 55. After the fifth episode of gastrointestinal bleeding, at the age of 63, she was transferred to Leeds General Infirmary and was noted to have hepatosplenomegaly and a few spider nævi on the face. She had never had jaundice or fluid retention and had always been mentally clear. Portal venography revealed patent splenic and portal veins with extensive gastric and œsophageal varices. Side-to-side portacaval anastomosis was performed by Mr. J. C. Goligher on Aug. 19, 1954. At operation the liver was noted to be grossly nodular. The patency of the anastomosis was confirmed by portal venography two weeks after operation, and the intrasplenic pressure fell to within normal limits (12 mm. Hg).

Two days after operation the patient suddenly became confused and violent for twenty-four hours. Three weeks later confusion recurred together with irregular coarse tremor of the hands and foetor hepaticus, followed within twenty-four hours by coma which responded to treatment with aureomycin and intravenous infusion of glucose.

Thereafter recurrent episodes of hepatic stupor and coma occurred; and during the five years following portacaval anastomosis forty such attacks were recorded, necessitating fifteen admissions to hospital; the longest period that the patient remained free from coma was fourteen weeks (fig. 1). In each attack she responded to omission of protein from the diet, large doses of antibiotics (initially aureomycin), and evacuation of the contents of the large intestine by enemas. Between these episodes she showed a variable degree of confusion and tremor despite restriction of the protein intake to 40 g. daily and, in the later years, continuous administration of neomycin. As a result of restricted diet her weight gradually declined; by 1959 she had lost more than 40 lb. in weight since portacaval anastomosis (fig. 1) and had developed ankle œdema.

Four times during the early part of 1959 the patient was admitted to hospital in hepatic coma, and on each occasion had been constipated for some days before admission. The response to treatment was noticeably slower than it had been in previous attacks, and apparently this was mainly due to

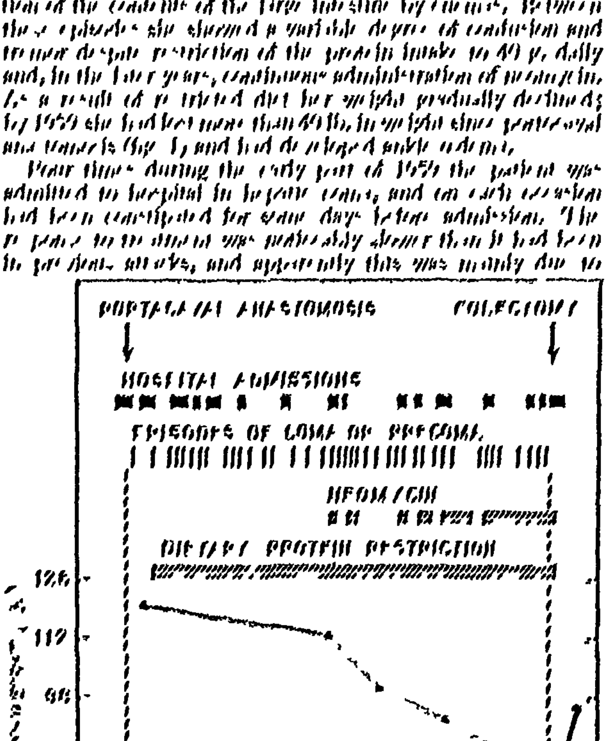

Fig. 1—Effect of colectomy in preventing further attacks of hepatic coma and in permitting the patient to take an unrestricted diet with consequent reversal of downward trend in body-weight.

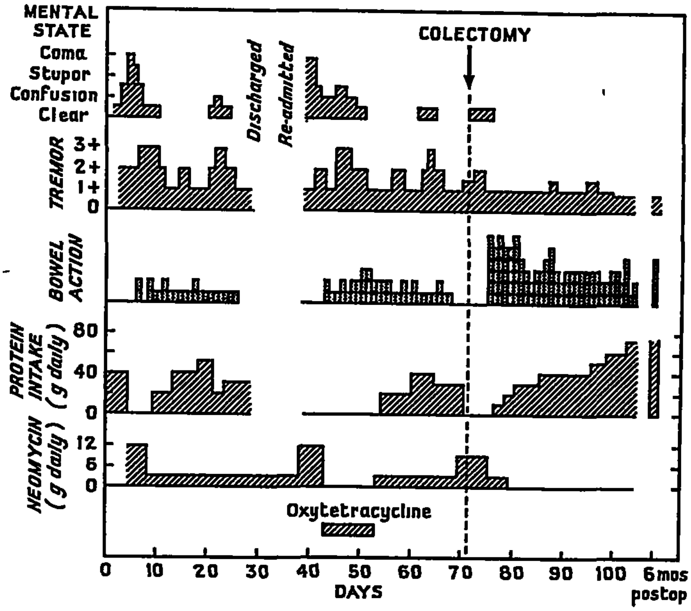

Fig 2—Effect of colectomy on protein tolerance assessed by changes in mental state and tremor

Before operation not more than 40 g of protein daily could be tolerated even when neomycin was taken. After operation protein tolerance exceeded 70 g daily and neomycin was not required.

difficulty in emptying the bowel. Repeated enemas were required to dislodge the hard fæces from the colon, but once these had been removed her neurological condition improved (fig 2).

As constipation appeared to play such a prominent part in precipitating hepatic coma and attempts to induce regular bowel habits with aperients and attention to diet had proved persistently ineffectual, it seemed justifiable to resort to surgical measures to correct this state of affairs, particularly as there were no other signs of impairment of liver function.

Colectomy with ileorectal anastomosis was performed on June 24, 1959. Exploration of the abdomen revealed a small fibrotic liver and a normal, rather visceroptosed colon. Total colectomy was carried out, with restoration of intestinal continuity by end-to-end anastomosis between the terminal ileum and the top of the rectum. Recovery after operation was entirely uneventful. Rather brisk diarrhœa in the immediate postoperative period soon gave way to more normal bowel function with about four loose stools daily and none at night. Hepatic coma or stupor have not recurred since colectomy, and the patient has shown progressive improvement in her mental state which is now clearer than at any time in the year preceding operation. Living alone she can manage her house and shopping without help. Neomycin is no longer required and she can take an unrestricted diet. Consequently the downward trend in body-weight has been abruptly reversed and the ankle œdema has disappeared (fig 1). Fœtor hepaticus disappeared completely after operation and has not recurred.

Some cerebral disturbance has persisted since the operation. Although well oriented in time and place and leading a moderately active life, the patient is emotionally labile and shows an inconstant tremor and dysarthria. Two brief psychological tests, the Mill Hill Vocabulary Scale (1948) and Walton and Black's Modified Word Learning Test (1957) were administered by Mr R. G. Webster six months after the operation. Her score of 42 on the former places her in grade III minus, indicating an average verbal ability. Her score of 31 plus on the latter test indicates that her capacity for word learning is impaired to a degree compatible with cerebral damage.

Nitrogen Metabolism

Absorption of the products of protein digestion appeared to be unimpaired after colectomy because the fæcal nitrogen excretion was within normal limits (the mean daily value being 0.91 g. over a six-day period).

Balance studies four months after operation, while the patient was on a protein intake of 60 g. daily, showed a positive nitrogen balance.

Protein Tolerance

During the preoperative period the protein tolerance was studied in relation to the neuropsychiatric state. The mental state and tremor were assessed daily by the same observer. During the period of observation regular bowel action was maintained by the use of aperients and neomycin was given. The results are shown in fig. 2, where it will be seen that before operation on two separate occasions neurological deterioration started when the daily protein intake reached 40–50 g. After colectomy the protein intake was gradually increased to the maximum the patient could eat (70 g.), without untoward effect even though neomycin therapy had been discontinued.

Fasting Blood-ammonia Levels

These were determined on peripheral venous blood by the method of Conway (1957). Five months before operation, on a day when the patient was in hepatic coma, the blood-ammonia was 3.0 µg. ammonia-nitrogen per ml. After maximum neurological improvement with medical treatment, the fasting blood-ammonia remained elevated and varied between 1.6 and 2.2 µg. ammonia-nitrogen per ml., the mean level being 1.8.

Five months after operation the fasting blood-ammonia had fallen to normal levels and varied between 0.7 and 1.1 with a mean of 0.9 µg. ammonia-nitrogen per ml. This reduction in blood-ammonia, particularly as it occurred despite cessation of neomycin therapy and return to unrestricted diet after operation, strongly suggested that bacterial catabolic activity in the gut had been greatly reduced by colectomy.

Methionine-tolerance Tests

Methionine, given orally, characteristically exacerbates the neuropsychiatric disturbance in patients with liver disease. This action appears to be due to products formed by the breakdown of methionine by the bacteria of the gut, because it is abolished by preliminary suppression of the intestinal flora with broad-spectrum antibiotics, and parenteral methionine is non-toxic (Phear et al. 1956). In our patient the

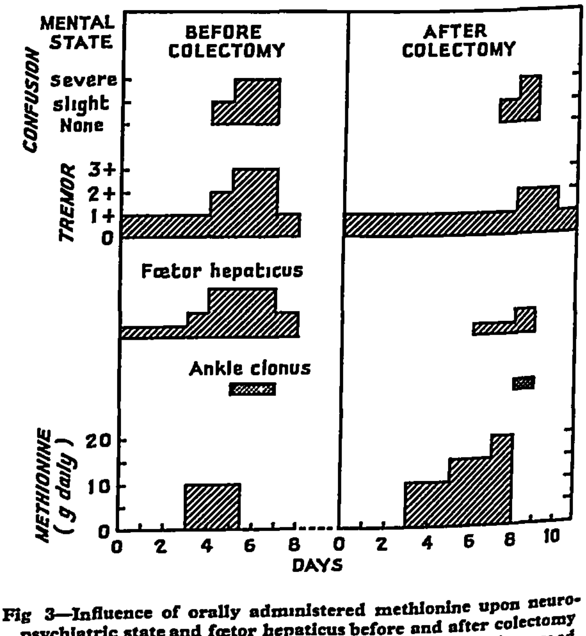

Fig 3—Influence of orally administered methionine upon neuropsychiatric state and fœtor hepaticus before and after colectomy. After operation methionine tolerance was considerably improved.

liability to develop neurological disturbance after methionine administration was used as an index of intestinal bacterial activity.

Before operation, at a time when symptoms were controlled by rigid dietary protein restriction alone, methionine was given by mouth in a dosage of 2.5 g. four times daily, and a daily examination was made to detect alteration in the neuropsychiatric state. On the third day of methionine administration, when the total dosage reached 25 g., mental confusion returned, tremor increased, and strong fœtor hepaticus developed (fig. 3). These rapidly improved when methionine was discontinued.

Five months after colectomy methionine tolerance was reassessed and was found to have improved greatly. Only after a total dosage of 75 g. did mental confusion occur together with increase in tremor and the appearance of fœtor hepaticus (fig. 3). The improvement in tolerance to oral methionine further confirmed that intestinal bacterial catabolic activity had greatly diminished after the operation.

Ammonium-tolerance Tests

A second and much less likely explanation of the fall in blood-ammonia levels and the improvement in methionine tolerance after operation is that liver-cell function improved about this time. This possibility seemed unlikely because the patient's response to oral ammonium chloride did not change. Before operation, when the neuropsychiatric state was controlled by dietary protein restriction and neomycin therapy, 2 g. of ammonium chloride three times daily caused obvious deterioration with return of mental confusion and increase of tremor on the second day, after a total dosage of 10 g. After operation ammonium chloride was given in a reduced dosage and similar deterioration was apparent on the third day, after a total of 9 g. The patient's ability to deal with ammonia absorbed from the gut was not increased after the operation.

Electroencephalographic Findings

The electroencephalographic pattern found in hepatic precoma or coma was described by Foley et al. (1950), Whitfield and Arnott (1951), and Bickford and Butt (1955). It has been correlated with the degree of neuropyschiatric disturbance (Parsons-Smith et al. 1957), the more severe this disturbance the greater the replacement of the alpha rhythm by slow theta and delta frequencies.

Electroencephalographic recordings were made four years, two years, and one week before colectomy, and two weeks, six weeks, and five months after colectomy. The preoperative records all showed typical changes with a dominant rhythm of 6–7 cycles per second bilaterally synchronous in the parieto-occipital and posterior temporal regions. An underlying alpha rhythm was still discernible. The earlier records were taken at times when the patient was grossly confused and precomatose, yet the record a week before colectomy, although taken after maximal improvement with medical treatment, showed no corresponding improvement in the electroencephalographic pattern.

The records taken after colectomy all showed persistence of the delta and theta frequencies, which were unchanged despite continued clinical improvement. Hence in this patient the electroencephalographic pattern did not appear to correlate with the degree of neuropsychiatric disturbance either before or after operation. Nevertheless, the persistence of such prominent electroencephalographic changes must be taken as confirming the clinical impression that some permanent cerebral damage has been sustained as a result of repeated attacks of hepatic stupor and coma before colectomy.

Discussion

In the early years of this century many clinical disorders were attributed to absorption into the general circulation of toxic substances produced by bacterial activity in the gut. Andrewes in 1913 stated: "The main effect of bacterial activity in the production of alimentary toxæmia lies in their ability to carry out protein cleavages beyond the capacity of the ordinary digestive ferments . . .", and Dixon (1913) mentioned ammonia and amines as such toxins normally dealt with by the liver. Arbuthnot Lane's (1909) application of colectomy to the treatment of the many diseases he ascribed to alimentary toxæmia resulting from "chronic intestinal stasis" aroused much controversy before this concept was eventually rejected. Amongst his patients was a woman unable to stand or walk and regarded as an imbecile who within a few weeks after colectomy, became happy, active, and intelligent (Lane 1912). The parallelism between this woman's case-history and that of our patient leads to the speculation that she had undiagnosed liver disease and therefore formed a counterpart to the present case.

In more recent years the susceptibility of patients with liver disease to neuropsychiatric disturbance when the dietary protein content is increased has been clearly recognised (Phillips et al. 1952, Sherlock et al. 1954), and the importance of bacterial activity in the gut in the formation of the offending nitrogenous toxins has been re-emphasised. The danger of constipation in precipitating symptoms, and the improvement which results from purgation, have been stressed by Dawson et al. (1957).

We have been unable to find previous reference to surgical treatment for colonic stasis in patients with neuropsychiatric complications of liver disease. Three operations were considered as a means to this end—simple terminal ileostomy, ileostomy combined with total proctocolectomy, and total colectomy with ileosigmoid or ileorectal anastomosis. Though either of the first two procedures might have been thought to offer a more certain prospect of eliminating intestinal stasis, they each had the serious drawback of involving the creation of an artificial anus, and the great attraction of the third operation was that it spared the patient this inconvenience. (This method was eventually favoured by Arbuthnot Lane [1909] in his surgical attack on intestinal stasis.) The occasion to perform colectomy in a patient without colonic disease had never hitherto arisen in our practice, but we had had considerable experience of colectomy and ileorectal anastomosis in the management of familial polyposis and selected cases of ulcerative colitis without rectal involvement. In such patients the operation is followed by mild chronic diarrhœa with normal anal continence, which is compatible with excellent general health and all ordinary activities. This operation was therefore chosen, and in the event has been followed by virtually no incapacity from frequent bowel actions.

Our observations emphasise that the products of protein digestion absorbed in the small intestine are not responsible for the cerebral disturbance in liver disease, after colectomy, despite the increased assimilation of protein, the neurological condition improved, thus clearly delineating the harmless and wholly beneficial process of protein digestion and absorption in the small gut from the potentially noxious one of bacterial degradation of the nitrogen residues reaching the large intestine.

Under normal conditions the bacterial content of the small gut is sparse (Cregan and Hayward 1953), but Martini et al. (1957) reported that in cirrhotic patients the flora of the ileum was increased and contained more coliform organisms and *Streptococcus fæcalis*. Conceivably our patient had an additional increase in ileal flora as a result of colonic stasis, and under these conditions relief of constipation by colectomy might in fact have reduced the bacterial content of the ileum The reduction in fasting blood-ammonia levels and the undoubted improvement in methionine tolerance both point to a drastic reduction in intestinal bacterial catabolic activity as a result of colectomy These findings could not be accounted for by a concomitant improvement in liver function, because the tolerance to administered ammonia remained unchanged after colectomy, and they *strongly suggest that the clinical improvement was due* to an overall reduction in the bacterial flora of the gut The ultimate prognosis in this patient may largely depend upon whether, and to what extent, the bacterial population of the small intestine increases in the future

The favourable results of colectomy in this patient suggest that this operation warrants a more extensive trial in patients with chronic or recurrent neuropsychiatric complications of liver disease It might be undertaken where medical measures have not controlled or prevented recurrence of symptoms, as in the present case Progressive undernutrition, resulting from prolonged restriction of dietary protein, might be taken as a second indication for colectomy, which, by increasing protein tolerance increases assimilation and thus improves nutritional status

Summary

Colectomy with ileorectal anastomosis controlled neuropsychiatric symptoms in a patient with recurrent attacks of hepatic stupor and coma, who five years previously had undergone portocaval anastomosis on account of portal cirrhosis with bleeding from varices

Protein tolerance was increased, and undernutrition, resulting from dietary protein restriction which had previously been necessary to diminish neuropsychiatric symptoms, was corrected

We are indebted to Dr M J Parsonage for the electroencephalographic studies, Mr R. G Webster, M A, for psychological assessment of the patient after operation, and Miss Brenda Stannard for assistance with the blood-ammonia estimations

"It is now increasingly realized that a large part of the study of 'handling human relationships' is a generic study, that is, it is the same kind of study for doctors, teachers, social workers, and so on What these professional training courses share ought not to be just a string of helpful academic disciplines, an attempt at making some pious cultural contributions, to ensure that our professional worker is 'well educated' They ought to be integrated into a coherent course of study which could then represent the highest common factor of general education for all professional courses"—PAUL HALMOS, *The Times*, Feb 15, 1960

HEPATIC COMA PRECIPITATED BY CHLOROTHIAZIDE IN HEPATIC CIRRHOSIS WITH ASCITES

S S MISRA
M D Lucknow, F R.C P
PROFESSOR OF CLINICAL MEDICINE

S P S TEOTIA
M B Lucknow
MEDICAL TUTOR

KING GEORGE'S MEDICAL COLLEGE, LUCKNOW, INDIA

THE development of hepatic coma has been described previously in patients with cirrhosis after administration of nitrogenous substances by mouth (ammonium salts, ammonium cation-exchange resins, urea, methionine, and increased dietary protein) It has also been reported in patients given drugs such as acetazolamide, barbiturates, opiates, paraldehyde, and tranquillisers Severe infection, upper-gastrointestinal hæmorrhage, and abdominal paracentesis have also precipitated hepatic coma, and mercurial diuretics are believed to be capable of inducing coma

Here we report the production of hepatic coma in patients with hepatic cirrhosis and ascites who had been given chlorothiazide, a non-mercurial oral diuretic agent designated chemically as 6-chloro-7-sulphamyl-1,2,4-benzothiadiazine-1,1-dioxide

Material and Methods

Chlorothiazide, 1 g was given orally twice a day, at 8 A M and 2 P M, to 12 patients—8 males (7 adults and 1 child) and 4 females (2 adults and 2 children) with cirrhosis complicated by ascites and peripheral œdema A history of past hepatic precoma characterised by confusion, drowsiness, disturbed consciousness, and flapping tremor was obtained in only 1 instance (table I) The diagnosis of cirrhosis was established by a history of past jaundice (hepatitis) and poor food intake coupled with clinical and biochemical findings In doubtful cases the diagnosis was confirmed by liver biopsy

Ascites was graded as follows severe, tense ascites with cardiorespiratory embarrassment, moderate, tense ascites, and mild, slight ascites

All patients were given a salt-restricted diet, fluids were not restricted. Urine was measured in twenty-four-hour amounts and saved for analysis Serum and urine were analysed for sodium and potassium by internal standard flame-photometry Serum and urine chloride concentrations were determined by silver-nitrate titration technique Diuretic response to chlorothiazide was assessed as follows excellent, œdema disappeared and no biochemical abnormalities or toxic effects developed, good, œdema disappeared but toxic effects or biochemical abnormalities developed, poor, œdema failed to clear completely or chlorothiazide was discontinued because of toxic effects or biochemical abnormalities

Only two stages of hepatic coma were differentiated impending coma (precoma), characterised by confusion, drowsiness, somnolence, and flapping tremor, and coma, characterised by violence requiring considerable restraint or unconsciousness with response only to painful stimuli or no response at all The regime of treatment in these patients consisted of (1) withdrawal of chlorothiazide (*precipitating* factor), (2) complete elimination of proteins from diet, (3) administration of oral antibiotics (tetracycline *2 g* daily), (4) removal of nitrogenous material in colon by enemas initially, and subsequent administration of magnesium sulphate by mouth, (5) fluid and caloric requirements (at least 1500 calories per day) supplied in the form of concentrated glucose solution given as drinks, by intragastric drip, or intravenously, (6) vitamin (B complex) supplementation, (7) potassium chloride given orally 4 g daily (caution was exercised especially if the volume of urine was diminished), (8) good nursing care.

TABLE I—CIRRHOTIC PATIENTS TREATED WITH CHLOROTHIAZIDE

"Recovery" from hepatic coma was defined as improvement sufficient for the patient to leave the hospital, or continued absence of coma or precoma so long as the patient remained in the hospital (average fifteen days).

Results

In 6 of the 12 patients the diuretic response was regarded as excellent (average weight loss 8 lb), in 2 as good (average weight loss 7·5 lb), and in 4 as poor (no weight loss). Chlorothiazide caused increased sodium, potassium, chloride, and urine excretion in all subjects; average twenty-four hour values during control and treatment periods are given in table II. Increase in urinary potassium output was associated with a fall in serum-potassium level in every patient except case 9, who received potassium supplements of 2 g. daily concurrently with chlorothiazide. The increase in urinary potassium and the drop in serum-potassium level were usually most rapid and conspicuous in those having the greatest diuresis. In cases 5 and 7, potassium excretion fell below control levels after cessation of drug administration, suggesting potassium depletion. No major change in serum sodium and chloride concentrations was noted (table III). The fall in serum-potassium was associated with a slight fall in serum sodium and chloride values.

Hypokalæmia, defined as a serum-potassium level below 3 mEq per litre, was noted in 4 patients receiving chlorothiazide without potassium supplements (table III). This state, although sometimes symptomless, is potentially dangerous.

Hepatic Precoma and Coma

This syndrome was noted in 4 of the 12 patients treated (table II). It was usually associated with a good and rapid diuretic response to chlorothiazide.

CASE 5 (fig. 1).—A woman, aged 42 years, with cirrhosis of liver with ascites and jaundice was admitted to hospital with splenomegaly and severe ascites with ankle œdema. There were no neuropsychiatric complications, hepatic fœtor, or flapping tremor, but there was a history of previous hepatic precoma. Chlorothiazide resulted in good diuresis (1800 ml. of urine, compared with 120 ml. in control period) and 2 lb. weight loss in two days. However, within forty-eight hours after starting to take the drug, the patient became drowsy and had slight hepatic fœtor and flapping tremor. The next day (fifty-eight hours after commencing the drug) she became violent, and extremely irritable and passed into a deep coma, regaining consciousness only after thirty-six hours of appropriate therapy.

* Potassium chloride 2 g. daily given concurrently with chlorothiazide.

CASE 7 (fig. 2).—This man of 30 years, with cirrhosis with severe ascites and ankle œdema and no past history of jaundice or hepatic coma, responded to chlorothiazide with a good diuresis (1200 ml. of urine compared with 150 ml. in the control period). But within seventy-two hours after starting to take the drug the patient exhibited hepatic fœtor, flapping tremor, and confusion with severe irritability, and in the next twelve hours he became very violent, requiring considerable restraint and passed into deep coma, regaining consciousness only after a hundred and twenty hours of appropriate therapy.

2 other patients (cases 1 and 10) exhibited hepatic precoma while receiving chlorothiazide.

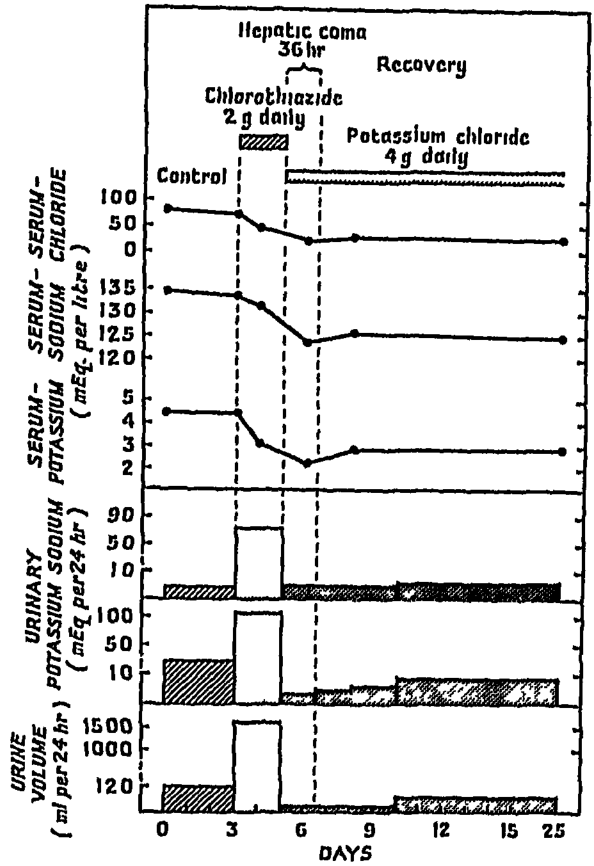

Fig. 1—Findings in case 5.

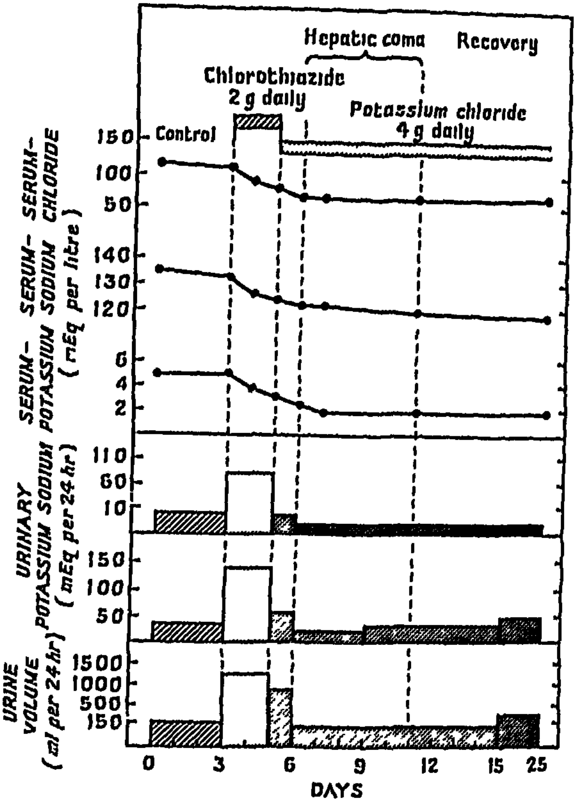

Fig 2—Findings in case 7.
The hepatic coma lasted for 120 hours

CASE 1 became drowsy and somnolent with numbness and tingling in the extremities. He was relieved of these symptoms within twenty-four hours by potassium supplements (table IV).

CASE 10 developed drowsiness which cleared up within thirty hours on administration of potassium supplements. Measurements of serum albumin, bilirubin, cephalin-cholesterol flocculation, and thymol turbidity showed no alteration in liver function during and after chlorothiazide administration (table V).

TABLE IV—EFFECTS OF POTASSIUM SUPPLEMENTS ON SERUM-POTASSIUM IN CASES OF PRECOMA AND COMA

9	6	2	3 2	6 2
10	5	2	2 2	3 5

Discussion

The results show that chlorothiazide can produce hepatic coma in cirrhotic patients with ascites The exact mechanism is not clear, but hypokalæmia and increased potassium excretion were a constant finding in the 4 present cases Hypokalæmia developing during administration of chlorothiazide to patients with cirrhosis and ascites has been observed by others Sherlock et al. (1958) noted the development of hepatic coma during administration of chlorothiazide in 7 out of 13 patients with a previous history of this syndrome; and others have described 1 or 2 cases each In our series hepatic coma developed in 4 out of 12 cases and only 1 patient had a previous history of this syndrome It is our impression that the hepatic coma produced in these cases was related to hypokalæmia and potassium deficiency, since administration of potassium chloride caused clinical improvement in the 2 cases of hepatic coma (cases 5 and 7) and prevented further hypokalæmia and hepatic coma in the 2 cases of hepatic precoma (cases 1 and 10)

Conclusions

Chlorothiazide administered to 12 patients with cirrhosis and ascites produced impending or actual hepatic coma in 4 This was associated with increased sodium, potassium, and chloride excretion and a fall in serum-potassium concentration

Recovery from impending hepatic coma was obtained by oral administration of potassium chloride 4 g daily

Chlorothiazide is a useful diuretic agent in patients with

cirrhosis and ascites, but patients must be carefully observed for the development of hypokalæmia and hepatic coma

In our opinion chlorothiazide therapy should not be given to cirrhotic patients outside hospital—particularly patients with a past history of hepatic coma or precoma Potassium chloride supplements 2–4 g daily should be given to avoid hypokalæmia, and special caution should be exercised if the volume of urine is diminished

Unfortunately chlorothiazide therapy is particularly dangerous in the patients with the most satisfactory diuresis

We wish to thank Dr K B Kunwar and Dr M M Singh for their valuable help and advice in all the phases of this work, and Mr R. P Srivastva for his technical help We are grateful to Merck, Sharp & Dohme for a supply of chlorothiazide, and to Unichem Laboratories, Bombay, for a research scholarship awarded to one of us (S P S T)

Determination of the specific gravity of the urine after a period of fluid deprivation has been widely used as an indirect indication of the concentrating-power of the kidney The osmometers now available enable workers to measure renal concentrating-power directly, in terms of osmotically active solute per litre of urine water With this method it was soon shown that urinary specific gravity is only roughly related to urinary osmolality (Miles et al 1954, Baldwin et al 1955, Isaacson 1959) But such studies of renal concentrating-power as now exist, measured in osmolar values, are few, involve small numbers of normal subjects, and have given differing results (Frank et al 1957, Boyarsky and Smith 1957, Dorhout Mees 1959) Accordingly, I have measured urinary osmolality in 63 apparently normal subjects, after an eighteen-hour period of fluid deprivation, in an attempt to supply definitive figures for this parameter of renal function

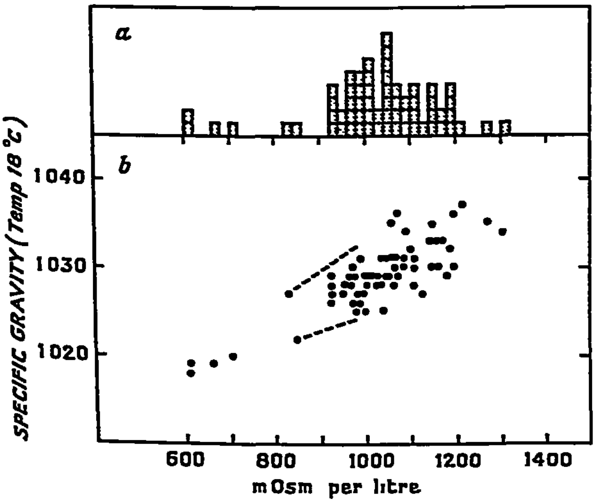

Fig 1—(a) Distribution of urinary osmolality in 63 apparently normal people, after eighteen hours' fluid restriction Each square represents one person. (b) Relations between urinary osmolality and specific gravity in the concentrated urines of (a).

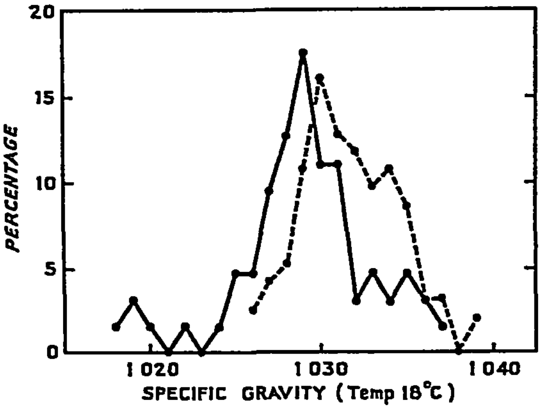

Fig 2—Distribution of specific gravity expressed as percentage of the number measured The dotted line represents a comparable series investigated by Addis and Shevky (1922)

63 medical students volunteered for the test. They were asked to abstain from all fluids or liquid foods from 12 NOON, to empty their bladders before going to bed, and to save a specimen of their early-morning urine next day They were to partake of their usual meals, without liquids, and to carry on with their usual activities Urinary specific gravity was determined with an ordinary clinical hydrometer, and osmolality with a Fiske osmometer, accurate to 1% All urine specimens were found to be free from sugar and protein

The results are shown in fig 1 57 (90%) of the students attained urinary osmolalities of over 900 milliosmols per litre The mean was 1027 mOsm (S D of 110 mOsm) The range was 610 to 1302 mOsm , 85% falling between 900 and 1200 mOsm

Different authorities give different levels for the urinary specific gravity which, after varying periods of dehydration, indicates adequate renal concentrating-power (see Fishberg 1954) Fig 1(*b*) shows that, while a rough correlation exists, the specific gravity may vary by as much as 0 006 for any given osmolality Urine concentrated to 900 mOsm per litre must have a specific gravity of at least 1 023, but only with specific gravity above 1 029 can one be sure that the urine has attained this osmolality

In 1922 Addis and Shevky recorded the range of urinary specific gravity in 75 normal subjects, after twenty-four hours' fluid deprivation Fig 2 shows the distribution of specific gravities obtained by me (expressed as percentages of the number measured) compared to that given by Addis and Shevky My adoption of eighteen hours' rather than twenty-four hours' fluid restriction resulted in slightly lower urinary concentrations From the known rough correlation between urinary specific gravity and osmolality, and the similarity of the curves in fig 2, we can infer that the range of osmotic concentration in the series studied by Addis and Shevky must have been very similar to, if somewhat higher than, that found in the present series

Summary

63 normal medical students were subjected to an eighteen-hour urine-concentration test Urinary concentrations of over 900 mOsm per litre were obtained in 90%, with a mean of 1027 mOsm (S.D of 110 mOsm)

Concentrated urines show only a rough correlation between specific gravity and osmolality Urine of 900 mOsm per litre must have a specific gravity of at least

1 023, but only at a specific gravity of 1 029 can one be certain that the urine has attained this osmolality

My thanks are due to Dr L Eales, associate professor of medicine in the University of Cape Town, for helpful criticism and advice

Cooke et al (1952) found that, during dietary potassium depletion in rats, the potassium leaving the muscle-cells was partially replaced by sodium, about 2 mEq of sodium passing into the cell for every 3 mEq of potassium passing out They postulated that the deficit of cation was corrected by hydrogen ions migrating into the cells, causing an extracellular alkalosis and an intracellular acidosis Black and Milne (1952) showed that extracellular alkalosis in experimental potassium depletion in man was not associated with increased loss of hydrogen ions from the body, and they suggested that the alkalosis was due to redistribution of hydrogen ions between the extracellular and intracellular spaces

Migration of hydrogen ions into muscle during potassium depletion should lower the intracellular pH, but actual measurements of the average pH of potassium-depleted muscle have given conflicting results Gardner et al (1952) and Schwartz and Wallace (1952) found that intracellular pH was reduced considerably in potassium depletion Darrow et al (1953) and Eckel et al (1959) reported that the pH was not reduced significantly below normal values All previous workers used a technique dependent on the distribution of free carbon dioxide and bicarbonate between plasma and muscle to which there are several theoretical objections and which is often inaccurate Waddell and Butler (1959) have introduced a method for determining muscle pH which is apparently more satisfactory, this is based on the distribution of a non-toxic weak acid—5 5-dimethyl-2 4-oxazolidinedione (D M O)—between plasma and muscle We have used this method to measure the intracellular pH of normal and potassium-depleted rat muscle and to confirm that in potassium deficiency the acidity of muscle-cells increases

Methods

Potassium depletion was produced in rats by the method described by Evans et al (1957), except that injections of deoxycortone acetate were not given A group of twenty-two albino rats, weighing 100–200 g , were used experimentally, and twenty litter mates served as controls There were two differences between the experimental group and the controls In the experimental group cation-exchange resin in the sodium phase (' Resonium-A ', Bayer) was added to the diet (30 g resin per kg of food), whereas the controls were not given resin but potassium salts (50 mEq per litre) were added to their drinking-water Plasma and muscle-cell pH was determined when the rats had had the experimental diet for 5–12 weeks

The method of Waddell and Butler (1959) for measuring muscle-cell pH was slightly modified as follows D M O 70 mg per kg body-weight and heparin 500–1000 units were injected intraperitoneally, and 3–4 hours was allowed for equilibration The rat was then rendered unconscious by a blow on the head and was bled immediately via a cervical incision, the blood being collected under liquid paraffin without any contact with air Blood pH was measured at 37°C by a glass electrode Muscle potassium and chloride were determined in 0 1 g and 0 5 g respectively of fat-free dry muscle solid prepared from voluntary muscles of the hind limbs

Statistical Analysis

Previous workers have regarded normal and potassium-depleted rats as two distinct groups, and have compared mean values from each group We applied this method of analysis in table I But in fact the potassium-depleted group was far from uniform, some rats being only mildly depleted of potassium and clinically healthy, others being obviously ill from severe potassium loss

The degree of deficiency is best measured by determination of the potassium content of muscle fat-free dry solid (F F D S) and this method of statistical analysis was used in table II and figs 1 and 2 The levels ranged from a high normal value of 475 µEq potassium per g F F D S to a grossly low value of 225 µEq potassium per g F F D S at the extreme of potassium depletion Thus plasma pH

TABLE I—STATISTICAL ANALYSIS OF MUSCLE-POTASSIUM, HYDROGEN-ION CONCENTRATION OF PLASMA AND INTRACELLULAR FLUID, AND HYDROGEN-ION GRADIENT IN NORMAL AND POTASSIUM-DEPLETED RATS

Comparison	Mean of normal rats	Mean of potassium-depleted rats	*t* value	*P*
Muscle-potassium (µEq per g F F D S)	447 (S D =18 1)	298 (S D =38 2)	3 9	<0 001
Hydrogen-ion concentration in intracellular fluid (moles per litre)	$11\ 98\times10^{-8}$ (S D =$3\ 58\times10^{-8}$) (Mean pH =6·92)	$20\ 20\times10^{-8}$ (S D =$10\ 36\times10^{-8}$) (Mean pH =6 69)	2 92	<0 01
Hydrogen-ion concentration in extracellular fluid (moles per litre)	$4\ 05\times10^{-8}$ (S D =$0\ 195\times10^{-8}$) (Mean pH =7 39)	$3\ 16\times10^{-8}$ (S D =$0\ 216\times10^{-8}$) (Mean pH =7 50)	5 62	<0 001
Hydrogen-ion gradient between intracellular and extracellular fluids (H_i^+/H_e^+)	2·96 (S D =0 89)	6 33 (S D =2 96)	3 8	<0 001

TABLE II—STATISTICAL ANALYSIS OF THE RELATION BETWEEN HYDROGEN-ION CONCENTRATION OF PLASMA OR VOLUNTARY MUSCLE TO THE POTASSIUM CONTENT OF MUSCLE F.F.D.S.

Regression against potassium per g F.F.D.S.	Gradient of regression line	Significance of difference from zero gradient	Correlation coefficient	Significance of correlation
Extracellular pH	−0·0006	$P<0·001$	−0·82	$P<0·001$
Intracellular pH	0·0013	$P<0·01$	0·54	$P<0·001$
Hydrogen-ion concentration in extracellular fluid	$0·0051\times10^{-8}$	$P<0·001$	0·81	$P<0·001$
Hydrogen-ion concentration in intracellular fluid	$-0·0404\times10^{-8}$	$P<0·025$	−0·35	$P<0·02$
H_i^-/H_e^+	−0·0216	$P<0·001$	−0·62	$P<0·001$
log H_i^+/H_e^+	−0·00194	$P<0·001$	−0·69	$P<0·001$

and muscle pH can be regarded as continuous variables dependent on the potassium content of the body.

The statistical methods were those described in the monograph by Snedecor (1956).

Results

Table I shows that there was an extracellular alkalosis and an intracellular acidosis in the potassium-deficient rats, the mean plasma pH being 0·11 units above control values, and the mean muscle pH 0·23 units below control. The hydrogen-ion gradient across the muscle-cell membrane was 2·2 times as great in the potassium-depleted as in the normal rats. All these differences are highly significant statistically.

Fig. 1 shows a linear relation when both plasma pH and muscle pH are plotted against the potassium content of muscle F.F.D.S. A more significant correlation is obtained if pH rather than hydrogen-ion concentration is plotted as ordinate, as shown in table II. Since plasma pH rises and intracellular pH falls with increasing severity of potassium depletion, the hydrogen-ion gradient across the muscle-cell membrane becomes progressively greater with increasing potassium loss.

In fig. 2 the hydrogen-ion gradient between intracellular and extracellular fluids expressed logarithmically (log $[H_i^+/H_e^+]$) is plotted against the potassium content of muscle F.F.D.S. Again a much closer correlation is obtained if the logarithm of the gradient rather than the gradient itself is plotted as ordinate. Table II shows that the gradients of the regression lines and the correlation coefficients are all significantly different from zero at a high degree of statistical probability.

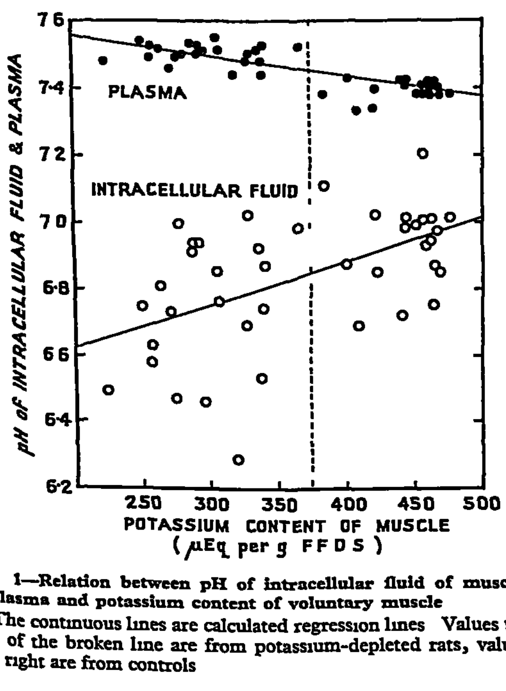

Fig. 1—Relation between pH of intracellular fluid of muscle or plasma and potassium content of voluntary muscle.

The continuous lines are calculated regression lines. Values to the left of the broken line are from potassium-depleted rats, values to the right are from controls.

The theoretical implication of these results will be discussed later in a more detailed paper. This account merely presents the experimental data showing that, as postulated by many previous workers and denied by others, muscle from potassium-depleted rats is significantly more acid than normal muscle.

Summary

A method, involving the distribution of the weak acid 5,5-dimethyl-2,4-oxazolidinedione was used to measure the intracellular pH of normal and potassium-depleted muscle in rats. Potassium depletion caused significant extracellular alkalosis and intracellular acidosis, with an increased gradient of hydrogen ion across the muscle-cell membrane. Better correlation with the degree of depletion was gained by using pH rather than the actual hydrogen-ion concentration, and the logarithm of the hydrogen-ion gradient rather than the hydrogen-ion gradient itself. The mean pH of normal muscle was estimated at 6·92, and of potassium-depleted muscle at 6·69.

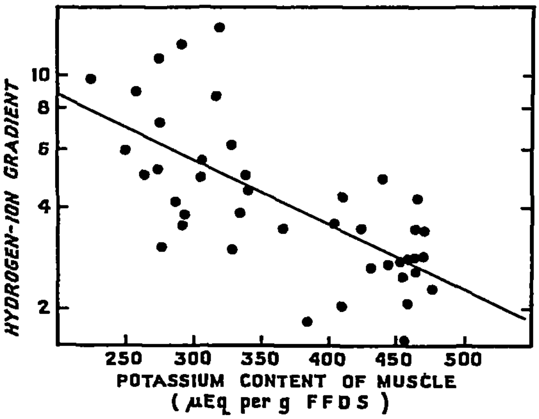

Fig. 2—Relation between the hydrogen-ion gradient across the muscle-cell membrane and the potassium content of voluntary muscle in normal and potassium-depleted rats.

The continuous line is the calculated regression line.

Thanks are expressed to Boots Pure Drug Company, and especially to Dr. J. Warwick Buckler, for synthesis of a pure sample of 5,5-dimethyl-2,4-oxazolidinedione.

Pharyngeal pouches are now usually treated by one-stage excision as advocated by Harrington (1945) When mediastinal infection was a more likely complication than it is today, invagination of the pouch was tried, in order to avoid opening the œsophagus (Bevan 1917), Hill (1917) suggested mobilising the pouch and suturing its distal end higher up the neck, to provide drainage from the sac into the œsophagus Neither of these two methods was widely adopted Two-stage excision, which was introduced by Goldmann (1908) and practised by Lahey (1940), was also performed in the hope that the complication of mediastinitis would be avoided More recently, diathermy excision of the septum between the pouch and the œsophagus, using a special œsophagoscope with a divided end, has been successfully carried out (Harrison 1956) When major surgery is contraindicated, and in the early stages of pouch formation, simple dilatation of the cricopharyngeal sphincter with an œsophagoscope may improve swallowing

We report a case in which a new operation has been tried for a very large pouch

Case-report

A man of 57, a hairdresser, presented with a five-year history of regurgitating food after meals, this symptom had become worse over the last year There was no spill-over into the larynx when he swallowed or at other times, and, although he had lost weight, his appetite was good and he remained at work He was thin (weight 107 lb) but there were no physical signs in the chest or neck Radiological investigations were made, and a barium swallow showed a very large pharyngeal pouch (fig 1)

Films taken during inspiration and expiration suggested that the pouch was adherent in the right side of the chest, films taken during a Valsalva manœuvre showed pharyngoceles (fig 2) There was also a congenital abnormality of the cervical spine, which showed fusion of the articular processes and the laminæ of the 5th and 6th vertebræ and narrowing of

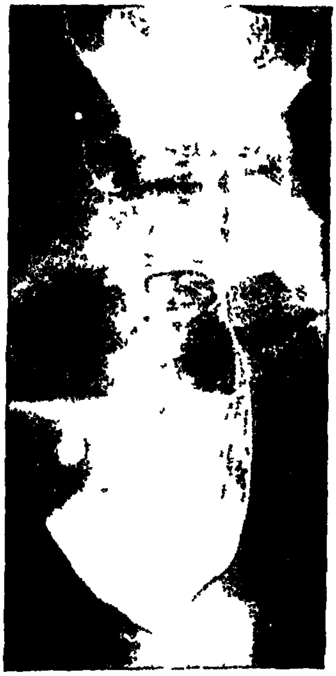

Fig 2

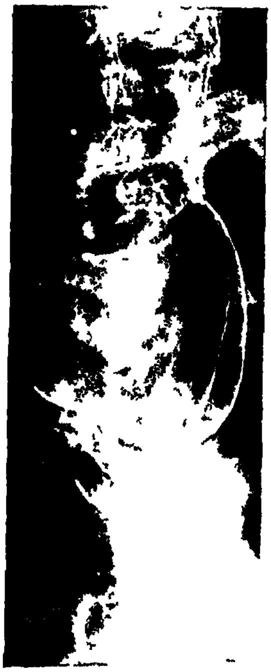

Fig 5

Fig 2—Anteroposterior view showing pouch and pharyngoceles during a Valsalva manœuvre

Fig 5—Barium swallow after operation, showing a satisfactorily functioning stoma

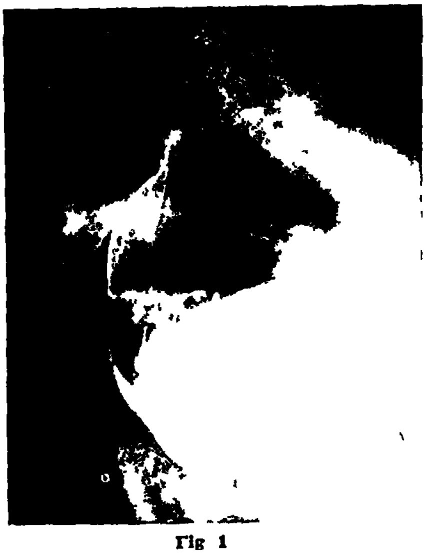

Fig 1

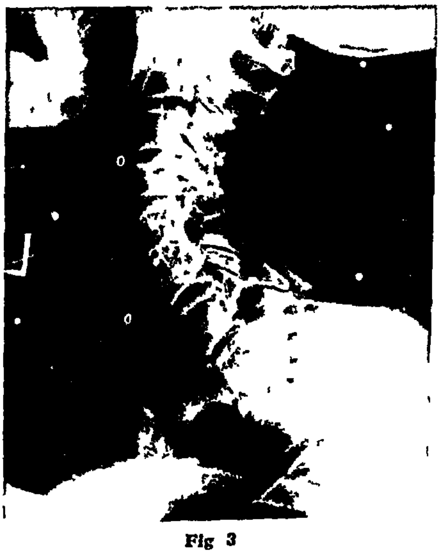

Fig 3

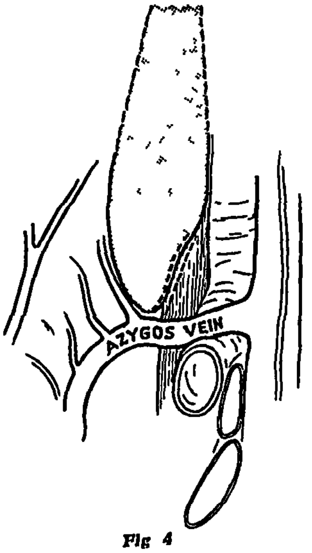

Fig 4

Fig 1—Lateral view of pharyngeal pouch containing barium

Fig 3—Lateral view of cervical spine, showing congenital abnormalities of the 5th and 6th vertebræ

Fig 4—Diagram of the right lateral view of the mediastinum, showing the pouch extending down to the level of the tracheal bifurcation and the site of the anastomosis to the œsophagus

the disc between them (fig 3) At œsophagoscopy the instrument passed straight into the pouch, which was clean and showed no signs of inflammation It was possible to move the œsophagoscope about in the upper part of the chest in a remarkable way, and to see the vertebral column bulging into the pouch posteriorly, the opening of the pouch into the œsophagus could not be found

When treatment came to be considered, it seemed inevitable that excision of the pouch would involve opening the chest and the neck, and though large pouches usually come up into the neck without difficulty, it was feared that this one might be adherent to a large vein One of us (R A W) therefore suggested that as a simpler alternative the lower end of the pouch should be anastomosed to the œsophagus in the chest This operation (diverticulo-œsophagostomy) was performed by Mr T Holmes Sellors on March 18, 1959

The chest was opened on the right side, along the upper border of the sixth rib, and after division of the azygos vein the pouch was easily identified, it extended downwards from the neck to the level of the tracheal bifurcation An opening was made at the lowest point of the pouch (empty except for two green peas), and a vertical incision was made in the œsophagus at the same level An anastomosis about $1^1/_2$ in long was then made between the pouch and the œsophagus (fig 4) A Ryle's tube was passed through the pouch and lower œsophagus into the stomach, and the chest closed with drainage The postoperative course was uneventful and a fortnight later the patient was swallowing solids well and had gained 10 lb

Ten weeks after operation he reported that he was eating normally and had gained 27 lb Another barium swallow showed a satisfactory stoma between the pouch and the œsophagus (fig 5)

Summary

A large pharyngeal pouch was treated by anastomosis of its distal end to the œsophagus in the chest

We are grateful to Mr C P Wilson, Mr R S Handley, and Mr T Holmes Sellors for permission to publish this case, to Mr A Turney for the photographs, and to Miss Hewland for help with the diagram

Preliminary Communication

HEART-SPECIFIC AUTOANTIBODIES

SINCE the claims of Masugi[1] and Cavelti,[2] there have been a number of reports of the presence of circulating autoantibodies in cases of heart-disease,[3] [4] none of them, however, showing the heart-specificity of the autoantibodies found.[5] Recently, Kaplan indicated the existence of two anti-heart autoantibodies in rheumatic patients, with specificity toward heart tissue[6] There is some evidence of production of anti-heart antibodies in experimental animals[7] [8]

We report here the production of antibodies to heart-muscle antigen in animals, the activity and specificity of such antibodies, and their presence in sera of human beings with and without heart-disease

MATERIAL AND METHODS

Immunisation —A group of mongrel rabbits was given 6 weekly injections subcutaneously of a homogenate of pooled rabbit hearts mixed with Freund's adjuvant[9] A second group received injections of buffered saline extracts of rat heart with and without adjuvant

Serology —Antigens were buffered saline extracts of minced organs Rabbit sera were examined by a modified Boyden's passive hæmagglutination technique (P H),[10] gel precipitation,[11] and complement-fixation tests Human sera were examined by the P H technique, fresh or after storage at −20°C for varying periods

Pathological effects —Possible cytopathogenic effects of rabbit sera were examined on 4–5 days old tissue cultures of rabbit or rat heart explants in clot In addition, histological examinations were made on the various organs of immunised rabbits

RESULTS

Rabbits Immunised with Rabbit Heart (table I)

In the P H test, two out of four rabbits gave high titres (up to 1/2500) with autologous and homologous heart extracts Lower titres were obtained with extracts of other mammalian hearts (rat, guineapig, dog, and human) and chick heart extracts gave the lowest titres Extracts of other rabbit organs gave negative results

Absorption of sera with heart extracts caused reduction in P H titre, while absorption with other organ extracts did not

Preincubation of sera diluted to half the P H titre, with heart extracts, caused the inhibition of the P H with heart extracts (hæmagglutination inhibition or H I test[12]) while extracts of rabbit lung, liver, and kidney did not show this effect

TABLE I—REACTIONS OF SERA OF RABBITS IMMUNISED AGAINST RABBIT HEART

Extract	Passive hæmagglutination	Gel precipitation	H I * with heart-sensitised erythrocytes
Rabbit heart	+	+	+
Other rabbit organs	0	+	0
Other mammalian heart	+	+	+

+ signifies positive result or, in last column, positive inhibition
* Hæmagglutination-inhibition

Complement-fixation tests showed only an insignificant rise in titre compared with preimmunised sera, while the gel-precipitation method gave positive results, both with heart extracts and with extracts of other rabbit and mammalian organs The reasons for this remain to be elucidated there is some evidence that these antibodies are different from the anti-heart antibody detected in the P H test

Rabbits Immunised Against Heterologous Heart Extracts

In addition to anti-rat (species-specific) antibodies shown by all serological techniques used, all four rabbits of this group showed anti-heart (organ-specific) antibodies in their sera as revealed by the P H technique These antibodies reacted with autologous heart extracts as well as with those of other animals The non-identity of the two groups of antibodies is shown by the results of the H I test (table II) Antibodies to rat heart were inhibited by extracts of rat heart but not by extracts of other rat organs or other mammalian heart Antibodies to "rat" were inhibited by all rat organs tested but not by other mammalian hearts, while "heart" antibodies were inhibited only by heart extracts

Pathogenic Actions

None of the sera of the immunised rabbits had a cytopathogenic action on rabbit heart cells in tissue culture However, the sera of rabbits immunised against rat heart extract did have a cytopathogenic action on cultures of rat heart cells

TABLE II—HÆMAGGLUTINATION-INHIBITION REACTIONS OF SERA OF RABBITS IMMUNISED AGAINST RAT HEART

Erythrocyte-sensitising extract	Inhibiting extract		
	Rat heart	Other rat organs	Other mammalian heart
Rat heart	+	0	0
Other rat organs	+	+	0
Other mammalian heart	+	0	+

+ signifies inhibition of hæmagglutination

No pathological lesions were found in the hearts of rabbits immunised with homologous heart extract, although some showed circulating anti-heart autoantibodies

The rabbits immunised with the aid of adjuvant showed the focal infiltrations in lungs, liver, and brain ascribable to the adjuvant [18]

Three Groups of Human Sera

1 *A case of post-myocardial-infarction syndrome.*—This is the Israel case referred to by Dressler [14] The serum had been stored at −20°C for 4 years. In the P H test with human heart extract, there was a strong positive reaction up to a dilution of 1/160 and a titre of 1/80 with extracts of other mammalian hearts (dog, guineapig, rat, and rabbit) Extracts of human and rabbit kidney gave negative results in this test The specificity of these antibodies for heart was shown in the H I. test (table III)—i e., they were inhibited by extracts of mammalian heart but not by extracts of other organs

A second serum sample, taken after 4 years' freedom from attacks, was negative

2 *Adults in hospital with heart-disease.*—These sera were examined fresh, against extracts of human and dog heart and human kidney

Three out of four cases of recent myocardial infarction and all of five cases of acute rheumatic activity (on a chronic background) gave *positive results Of eight patients with* myocardial insufficiency, anginal syndrome, and the like, five were positive

Only one of five cases of inactive rheumatic or congenital heart-disease was positive when examined immediately before or after cardiotomy This patient had had recurrent congestive heart-failure for some years.

As a control, fifteen sera sent to the clinical laboratory for a variety of tests (e g , rhesus group in pregnancy) were examined Two of these gave a positive P.H test

All the positive sera reacted with both human and dog heart extracts Some of them reacted, too, with kidney extracts As in no case the titre was higher than 1/10, further characterisation of antibody specificity was not possible

3 *Children with non-active rheumatic heart-disease*—The sera had been taken up to 2 years previously from children in a communal settlement with a high prevalence of rheumatic heart-disease. All the children had received continuous chemoprophylaxis and none had detectable albuminuria Nine out of twelve gave positive reactions similar to those described in the adults (group 2).

Of fourteen sera from apparently healthy children from the same settlement, four gave positive P H tests

COMMENTS

It is hard to conceive of an autoimmune reaction that is not linked to a specific antigen, such as is involved in diseases of lens,[15] testis,[16] brain,[17] and thyroid [18] Among the few investigators successful in demonstrating autoantibodies in heart-disease, only Kaplan has shown their organ specificity [6 7] In his case, however, the antigen was particulate and insoluble in saline, unlike those described here

TABLE III—HÆMAGGLUTINATION-INHIBITION REACTIONS IN CASE OF POST-MYOCARDIAL-INFARCTION SYNDROME

Erythrocyte-sensitising extract	Inhibiting extract		
	Human heart	Human and Rabbit kidney	Other mammalian *heart*
Human heart	+	0	±
Dog heart	+	0	+

+ signifies complete, ± *partial, inhibition of hæmagglutination*

The concept [19] of autoantibodies as a cause of disease is *not* supported by our finding circulating anti-heart *antibodies in rabbits* without any pathological change in the heart Probably these autoantibodies are a consequence rather than a cause of tissue destruction The pathogenic autoimmune reaction may be due to the action of cell-bound antibodies [20] or "forbidden clones" as suggested by Burnet [21] Be that as it may, the presence of circulating organ antibodies may be assumed to indicate autoimmune disease

A striking finding in the present experiments was the similarity in the anti-heart antibodies produced by immunised rabbits and by the patient with post-myo*cardial-infarction syndrome This seems to support* Dressler's suggestion [14] that the syndrome is due to an autoimmune reaction, though the initiating stimulus here is different from that in the experimental animals

The low hæmagglutinating titres found in other positive human sera prevented characterisation of the antibodies, but they may be identical with those described by Dornbusch [4] Absence or low titre of antibody may be attributed either to adsorption of antibody on heart tissue or to inability to react to this specific antigen

Thanks are due to Prof A Laufer for the histological examinations and to Dr D Nelken for his helpful advice The experimental work in this communication forms part of the subject of the PH D thesis of one of us (I G)

ADDENDUM

We have since found three further cases with high titres of specific heart autoantibodies similar to those found in the case of post-myocardial-infarction syndrome Two of *the cases suffered recent myocardial infarction* and the third had recently undergone mitral valvotomy

" Among the professions, your best opportunity, moneywise, is to be a doctor In fact when it comes to money, it is better to be an independent physician than just almost anybody General practitioners on the average net around $16,000 a year, surgeons average about $35,000 (Psychiatrists average only $17,000, perhaps because their patients individually take up more of their time than ordinary patients) Most specialists average several thousand more Why have medical practitioners succeeded in pulling so far ahead of other professionals? A scarcity—an artificial one, some charge—has been created In 1900, there was one licensed doctor for every 578 people By 1940 the proportion of doctors had shrunk to the point where there was one for every 750 patients, or, if you consider only those still in active practice, there was one active doctor for every 935 persons "—VANCE PACKARD, *The Status Seekers*, p 99 London, 1960

Reviews of Books

Essential Principles of Pathology

JOHN W LANDELLS, M.B, M R C.P, reader in pathology in the University of London at The London Hospital London Pitman Medical Publishing Co 1959 Pp 278 25*s*

SOME will be tempted to dismiss this as a cram book, but they would be very wrong, for though it is cheap and could serve as efficiently as any cram book it is in fact an honest and well-thought-out attempt to produce a real introduction to pathology at a level which enables the slower undergraduate to read with profit. Too often "introductions" to pathology deal almost exclusively with principles, disregarding the fact that basic principles can be terribly hard things to grasp *first*, and that in subjects like pathology it is often best to build foundations after the ground floor Judging fairly accurately the capacity of the average student, Dr Landells has not included all the things he thinks ought to be learnt, but as many as he thinks will in practice be learnt

Standard textbooks of pathology have been written by men who in their time were outstandingly intelligent undergraduates, and, good though some of the available examples are, many textbooks seem to be concerned less with helping the student with pathology as a subject he meets in his course and more with serving him as a reference text for the rest of his life They aim to be accurate, judicious, and, above all, to leave nothing out too often it is the criticism of fellow pathologists that the author fears, rather than that of more junior readers For the bright student who is best on a tough diet, they are excellent, but they are heavy going for the average, and often nearly unintelligible to the tail end Dr Landells seems to be attempting to reproduce the kind of teaching, simplified when it can be honestly simplified, that a conscientious teacher well in touch with his audience tries to give when early flourishes are over and examinations loom His 270 uncrowded pages cover most of what can be expected certainly few examiners could fail a student who was thoroughly familiar with this book One difficulty is that no two pathologists would agree as to what are the *essential* facts of pathology, and in an attempt to retain the immediacy of verbal teaching Dr Landells occasionally lapses into sentences that will irritate some readers A few of his classificatory passages are of questionable logic But this is a book that sets itself a worthwhile though smallish target, and hits it fairly Undergraduates who have no hankering after distinctions should welcome it

Antibiotic Therapy for Staphylococcal Diseases

Editors HENRY WELCH, PH D, editor of *Antibiotics and Chemotherapy*, Washington, D C, MAXWELL FINLAND, M D, associate professor of medicine, Harvard Medical School New York Medical Encyclopedia, Inc London Interscience Publishers 1959 Pp 208 34*s*

ANTIBIOTIC-RESISTANT staphylococcal infections have now reached formidable proportions, they complicate operations, contaminate hospital nurseries, and exalt the virulence of influenza epidemics Staphylococci spread on the skin, persist in the nose, and circulate in the blood, whence they may settle with disastrous effect in brain and bone Their disregard of antibiotics has placed all those concerned, from pædiatrician to geriatrician, in a position of growing anxiety against mounting morbidity and mortality Various steps to reduce the hazard include vigilance against cross-infection, combinations of antibiotics, rotation of drugs, measures to improve host resistance, and, fortunately, some new antistaphylococcal agents

This authoritative monograph gives a critical account of the problem and evaluates the six latest antibiotics to join the fray—erythromycin, oleandomycin, novobiocin, vancomycin, ristocetin, and kanamycin. The six chapters describing them are the most modern and comprehensive accounts available In an opening chapter, Dr Welch outlines the development of the staphylococcal menace and the impact of earlier antibiotics upon it And finally Dr Maxwell Finland compares the relative value of the various antistaphylococcal drugs and provides a perspective for those who are bewildered as well as bedevilled by the staphylococcus

Statistical Methods in Biology

NORMAN T J BAILEY, D SC, reader in biometry, University of Oxford London English Universities Press 1959 Pp 200 25*s*

THIS short book provides a clear account of the principles underlying the standard statistical methods and the steps required for the calculations Using a minimum of mathematics, Dr Bailey illustrates the techniques with examples from various fields of biology and medicine The topics covered are orthodox (occasionally, even, old-fashioned), but two valuable innovations are introduced There is an excellent chapter on computing and on the use of desk calculating machines, and a final section of the book, on green paper, contains a glossary, some necessary tables, and a 26-page summary of the methods described earlier This is one of the best books of its type

Recent Advances in Public Health

2nd ed J L BURN, M D, D HYG, D P H, medical officer of health, City of Salford London J & A Churchill 1959 Pp 370 40s

THIS book has been entirely rewritten, and it is misleading to call it a second edition, twelve years after the first, when its function is to tell about recent advances It does so in a very pleasant style, and, in addition to the usual references, there are suggestions about books and published papers for further reading, and a most useful list of voluntary organisations willing to help Dr Burn has intentionally restricted the scope of his book to give a more detailed account of the advances on a narrower front, the practical day-to-day working of some of the public-health services at local level in Britain The balance between the individual, the community, and the environment has come down heavily with emphasis upon the personal services, personal relationships, and clinical involvement No doubt that truly reflects the preoccupations of the National Health Service in its first ten years Some of the advances have taken the public-health services deep into the therapeutic spheres of the hospitals and general practitioners, usually by that happy multiprofessional cooperation which runs as a theme of hope throughout the book. It may be hard for the public-health service to find the time, or be able, to untangle itself to meet the wider challenge of modifying man's environment to meet the needs of man Ionising radiations just throw their shadow across only a corner of the text

This is a book for the public-health practitioner rather than the student, as any evaluation of advance must be It demands some established experience to keep the sophisticated minutiæ of British personal services in perspective with the greater epidemiological and environmental changes in the world today, and to see that there is ample scope for advance on a broader front, with perhaps good hope of a breakthrough before the next edition Dr Burn concludes with a timely reminder that the promotion of health is a bigger concept than the mere prevention of disease There is a lot in this book to turn to for refreshment and to think about.

The Archetypes and the Collective Unconscious

C G JUNG The collected works vol 9, part 1 Editors SIR HERBERT READ, MICHAEL FORDHAM, M.D, GERHARD ADLER, PH D Translated by R F C HULL London Routledge & Kegan Paul 1959 Pp 462 52*s* 6*d*

THIS large and beautifully produced volume is rich in format and in content, and brings together writings of Professor Jung formerly published in journals and books The text consists of six sections the first includes papers on archetypes of the collective unconscious and the concept of the collective unconscious, section 2 deals with psychological aspects of the mother archetype, section 3 is concerned with rebirth, section 4 with the psychology of the child archetype and the psychological aspects of the Kore, section 5 is on the phenomenology of the spirit in fairy tales and the psychology of the trickster-figure, and section 6 contains chapters on conscious, unconscious, and individuation, and a study in the process of individuation There are 80 plates, 29 in colour, and 5 figures

Anyone familiar with Jung's ideas will be delighted with this book, while to the sceptic or the novice the chapter in section 1, on the concept of the collective unconscious, may be recommended as an introduction (appropriately enough, it is the text of a lecture given to the Abernethian Society at St Bartholomew's Hospital)

The Golden Age of Quackery

STEWART H HOLBROOK London and New York The Macmillan Company of New York 1959 Pp 302 34*s* 6*d*

EIGHTY years ago the United States was expanding at a rate greater than that of any nation in the history of the world Its population was increasing by more than a million a year, and, numerically and geographically, much of that population had outstripped its supply of doctors Many of its inhabitants were comparatively wealthy, but ill educated (In 1870, the head of Harvard Medical School was reported as saying that " written examinations could not be given because most of the students could not write well enough ") This was the *Golden Age of Quackery* of Mr Holbrook's title, the heyday of the patent-medicine maker

Unhampered by any licensing or narcotic laws it was possible at this time for unscrupulous manufacturers to sell " tonics " which derived most of their effect from being 50% alcohol, to compound " cures for the liquor habit " which owed their efficacy to a heavy dose of morphia, and to brew " cough syrups ", each bottle of which contained a lethal dose of opium Stimulated by widespread and sustained advertising, the demand for such preparations could be raised to the point when it was difficult (even, in one case, for an organisation employing a thousand people) to meet it Nor was the market for these medicines restricted to the ignorant or the unlettered In 1861 the commissariat of the Union Army bought Hostetter's Bitters, the " Anti-Bilious Alterative " by the car-load The most notable feature of this nostrum was its 47% alcohol content, and a Civil War historian was later to write that " its vaunted remedial properties were sadly lacking but many a frightened Yankee at Gettysburg knew he faced Pickett's Charge as bravely as he did because of the swig of Hostetter's under his belt "

This book, by a distinguished authority on several aspects of American life at this time, gives an unusual and amusing account of these bogus remedies, of the picturesque medicine shows, the anatomical museums, and a host of devices calculated to assist in the task of parting the gullible from their money The Golden Age ended abruptly on Jan 1, 1907, when the Federal Pure Food and Drug Act became law And let any reader on this side of the Atlantic, who is inclined to smile at the credulity of his American cousins, reflect that comparable legislation in this country was delayed until 1941

Tools of Biological Research (Oxford Blackwell Scientific Publications 1959 Pp 183 37*s* 6*d*)—Edited by Mr H J B Atkins, this book records the proceedings of the successful symposium held at Guy's Hospital in October, 1958[1]

New Inventions

A TREPHINE NEEDLE FOR VERTEBRAL BODY BIOPSY

A MODIFIED trephine needle has been devised to overcome the defects of the method of aspiration biopsy described by Valls et al[1] With this method only small quantities of material can be obtained for examination, and in sclerotic lesions the needle cannot penetrate the cortex of the bone

With the new instrument larger samples can be taken from any type of vertebral lesion without injury to the patient

The needle has four parts (fig 1)

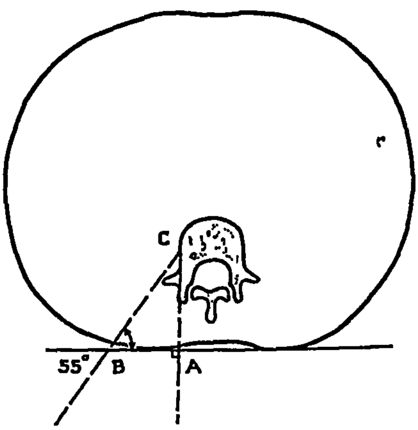
The needle holder (A) is a steel rule, boldly marked in centimetres, with a needle holder at one end fixed at an angle of 55° to the horizontal A sliding pointer makes it possible to adjust the distance from the mid-line at which the needle enters

The biopsy needle (B) is 16 cm in length and 3 mm in diameter and is marked in centimetres It has sharp cutting teeth at the distal end, and a milled circular head to facilitate gripping when the cortex of the bone is trephined

The exploring needle (C), which is 17 cm in length and 2 mm in diameter, is headless to permit the biopsy needle to slide over it when correctly placed

The infiltrating needle (D), which fits within the exploring needle, is used for infiltrating with local anæsthetic as the exploring needle is advanced It is withdrawn before the biopsy needle is inserted over the exploring needle

The position of the needle for biopsy is determined from a previous X-ray examination in which a steel rule has been included to allow for distortion The important factor is the point of entry, which must be some distance from the midline to avoid the transverse processes It may be calculated as suggested by Ray[2] the depth of the vertebral body is measured on the plate, and, as the needle is fixed at a known angle, the other measurements can be calculated trigonometrically (fig 2)



$$AB = \frac{AC}{\text{Tan } 55^\circ} = \frac{AC}{1\ 43}$$

$$BC = \frac{AC}{\text{Sin } 55^\circ} = \frac{AC}{0\ 82}$$

Fig 2

In practice, a piece of bone measuring 1 cm × 2 mm is obtained without difficulty this is large enough to show the trabecular pattern as well as to permit a wide field for examination of the cellular structure

This needle and several prototypes have been developed with the assistance of Mr J G Edwards, of the Edwards Surgical Company, 289, City Road, London, E C 1, and various members of the staff of the Orpington and Farnborough Hospitals, Kent, to whom I am greatly indebted

The Unclaimed

OF the world's two and a half million unsettled refugees about a hundred thousand are on our doorstep, in Europe Some have been Stateless sojourners for fifteen years, leading a half-life without home or work or hope, and a new generation is growing up which has known no other way Many organisations and workers are striving to end their plight, and, if what they have done falls short of the need, it is largely because they have been denied the means of doing more This is not necessarily due to imperviousness the opening of doors to Hungarians who left their country in 1956 showed that, when the imagination is fired, people will respond, and the success in some countries of appeals in the World Refugee Year betokens growing uneasiness about those who remain in temporary refuge

One fact is clear the four European countries which have unsettled refugees in large numbers—Greece, Italy, Austria, and Germany—cannot provide satisfactorily for all of them Ungrudgingly these countries continue to give asylum to new refugees whose status under the United Nations mandate is established Italy, far from rich, with 2 million unemployed or under-employed and with some 400,000 of her own citizens from overseas accommodated in camps, yet shelters and feeds 5000 unsettled refugees and accepts new ones as they cross the border About 90% of these emigrate, but 10% remain and are an added charge on the country's resources If Italy and her neighbours are prepared to grant asylum, so should others be the responsibility is international.

This international responsibility cannot be fulfilled so long as the present immigration laws are retained Designed to protect native populations, these laws are archaic, futile, and harsh Their archaicism is evident from their insistence on freedom from signs of pulmonary tuberculosis Their futility is reflected in the experience of the Hungarian exodus, when thousands were allowed to cross borders with scant regard to security or medical checks no country seems to have been endangered or put to great expense Their harshness is shown by acceptance under them of the young and the fit while their less able relatives are excluded Such negative selection is not only inhumane but also unfair it is inhumane because it tends to split families, and it is unfair because it leaves the handicapped to the care of the overburdened first country of asylum An early objective should be to secure that would-be immigrants are not considered as individual units, and that no family is barred from immigration simply because it has one or more disabled members after all, no family need cost the second country of asylum anything if a breadwinner can support his relatives One or two countries, recognising this, have already gone some way towards amending their immigration laws

Relaxation of these laws will not by itself enable all the "hard core"—those who have been rejected for immigration under mass schemes—to settle in a second country But we should free our minds of any idea that these people will necessarily be a burden on the community impaired vision in one eye, loss of a kidney, an untreated hernia, a healed tuberculous lesion, a stiff knee—these barriers to immigration under mass schemes do not prevent useful work On the other hand, the "hard core" also includes some—such as "unaccompanied" mothers with children—who will less certainly be self-supporting In the survey which appears on p 481 of this issue we suggest that priority should be given to these, to the tuberculous, and to the ageing and elderly—those over 45, unacceptable under mass schemes, who are not always fit for the heavy work which is all that can be offered in some of the first countries of asylum But the aim, with other countries, should be no less than the acceptance of all refugees who wish to leave the Continent And common sense tells us that this task should be undertaken at once, for an employable person who is unemployed—as many at present are—is a needless charge on the community, and the longer he remains unemployed the harder will he find it to resume work

Europe's "refugee problem" can be solved and solved quickly, but only if more money is forthcoming and if nations deliberately accept more of the handicapped The Office of the United Nations High Commissioner for Refugees has been making good use of relatively small sums subscribed by individual Governments, both for resettlement and for integration Of our own voluntary bodies, the non-denominational Adoption Committee for Aid to Displaced Persons is noteworthy as the first organisation to have applied substantial sums to the resettlement of those in unofficial German camps—who, as a group, are perhaps in greater need than any other In our review we suggest that on the Continent refugees might be better served if the dozen or so main voluntary agencies worked in closer union The same may be true of voluntary bodies in this country If in this World Refugee Year the many British organisations had launched a united appeal instead of raising funds on their own behalf and at the same time participating in the appeal by the central committee, the impact would undoubtedly have been greater Is it too late to take a leaf from the copybook of Norway, which has a single refugee organisation? With its small population of $3\frac{1}{2}$ million, Norway has an unparalleled record for accepting handicapped refugees, and in this World Refugee Year £520,000 was raised in the first drive So far the per-caput contribution is highest in Norway, where it amounts to nearly 4*s* Norway is followed by Sweden, the Netherlands, and New Zealand The United Kingdom comes fifth, with about $10\frac{1}{2}$*d* per head our original goal of £2 million has lately been reached, and the goal has now been set at £4 million

We look back on the Victorian era as one of contrast between riches and slum poverty We should not let our grandchildren recall mid-20th-century Europe as a place of general prosperity with small islands of destitute Stateless people whom no nation claimed If this is to be avoided the flame which burned briefly in 1956 must be rekindled and kept alight the acceptance of Hungarians in that year (though the motives may not always have been purely humanitarian) is the one example of almost unreserved international effort Settling Europe's refugees will give us heart and confidence for the vaster issue of the two million in the Middle East and Far East In this endeavour let us be informed by EDMUND BURKE " It is not, what a lawyer tells me I *may* do, but what humanity, reason, and justice, tell me I ought to do "

[Contributions may be sent to the United Kingdom World Refugee Year Committee, 9, Grosvenor Crescent, London, S W 1]

Peptic Ulcer in Town and Country

METHODS of estimating the frequency of peptic ulcer all have serious limitations, and the overall and regional prevalence of this common condition remains unknown Mortality, clinical, and necropsy statistics are almost always made within selected hospital populations, and varying standards of examination and diagnostic criteria reduce their value Population surveys, though expensive and time-consuming, probably provide the best basis for estimation, but they are limited by the fact that the criteria for the diagnosis of ulcer are by no means precise Notable in the field of population surveys of ulcer frequency has been the work of C N PULVERTAFT [1] in York As a sequel to the pioneer work done in that city by VISICK [2] on the surgery of peptic ulcer, PULVERTAFT, with the help of medical and surgical colleagues, has managed to collect all new peptic ulcers developing in the city of York and in the surrounding country districts of Easingwold, Flaxton, and Pocklington in the five years 1952–57 As the size of the total population at risk was known it was possible, probably for the first time, to estimate ulcer frequencies accurately in an unselected population—105,371 in the city of York and in 33,335 people in the country area Particularly stringent diagnostic criteria were observed throughout ulcers were judged to be present when they caused acute perforation or hæmorrhage, when they were found at necropsy, gastroscopy, or operation, or where they were convincingly demonstrated radiologically

In the five years 1132 ulcers were found, 823 in men and 309 in women Diagnosis rested, in both sexes, on clinical grounds in 3 out of 4 patients and on hæmatemesis in 1 in 6 The proportion of women with acute perforation (7 8%) was appreciably less than in men (13 7%), possibly because duodenal ulcers, which perforated more often, were relatively less common in women Of the 823 ulcers demonstrated in men, 658 were duodenal, 126 gastric, and 31 antral, and 8 had combined gastric and duodenal ulcers Of the 309 ulcers in women, 204 were duodenal, 89 gastric, and 11 antral, and 5 had ulcers in both sites The mean annual incidence per 1000 population aged 15 years and over was, for duodenal ulcer, 2 15 in men and 0 62 in women, and, for gastric ulcer, 0 53 in men and 0 31 in women.

Age had an important bearing on incidence There seemed in men to be an equal liability for duodenal ulcer to develop at any age between 25 and 64, and the risk was appreciably less under 25 or over 65 Gastric ulcers, in contrast, developed more often in men between the ages of 45 and 64 Women began to have symptoms from duodenal ulceration most commonly between 35 and 44, and ulcer frequencies remained high in postmenopausal and elderly women Gastric ulcers increased in frequency in women with advancing years, occurring most commonly in the elderly and middle-aged The increased frequency of ulcer and ulcer complications at the time of the menopause was emphasised by CLARK [3] The overall age-incidence of ulcer in both sexes was remarkably similar to that in the necropsy data of WATKINSON [4] [5]

The influence of social class on the incidence of gastric ulcer had previously been demonstrated by MORRIS and TITMUSS [6] and by DOLL and others,[7] both groups being unable to show any similar relation for duodenal ulcer In the York survey the occurrence of both types of ulcer seemed to be influenced by social and occupational factors Thus, duodenal ulcer in men increased from 2 08 per 1000 in professional and semiprofessional classes, to 2 26 in artisans, and to 3 13 in semiskilled and unskilled workers Differences were even more striking in gastric ulcer, which increased in these groups from 0 34 per 1000 in professional and semiprofessional classes to 0 92 per 1000 in unskilled or semiskilled artisans The decreased liability of agricultural workers to ulcer, reported by DOLL et al ,[7] was not confirmed in the country district around York

Striking geographical differences in the frequency of peptic ulcer have been reported in several countries DOGRA [8] found that ulcer arose more commonly in Southern than in Northern India, and KONSTAM [9] reported more ulcers in Southern than in Northern Nigeria In Europe similar regional differences were reported from Sweden,[10] Italy,[11] and Denmark [12] In England in 1944, MORRIS and TITMUSS [6] demonstrated lower mortality-rates from ulcer in rural than in urban communities WATKINSON,[4] by a forward-planned necropsy survey undertaken at selected hospitals in England and Scotland in 1956, found that duodenal ulcer was significantly more common and caused more deaths in northern than in southern cities—a difference more striking in men than in women, and for duodenal than for gastric ulcer

Despite the difficulties of comparing clinical estimates of ulcer frequency with material collected in other ways, PULVERTAFT [1] felt able to draw a few limited analogies to illustrate that regional differences might appear Thus, the frequency of acute perforation in duodenal ulcer in men in York appeared appreciably higher than in Glasgow[13] and Aberdeen[14] but no similar trend was noted in women Gastric ulcers perforated more commonly in York in both sexes When comparing his clinical ulcer frequency with the necropsy material collected by WATKINSON[5] in Leeds between 1930 and 1949, PULVERTAFT used for comparison the frequency of chronic active ulcers found incidentally at necropsy, since these subjects might well have had ulcer symptoms in life and their death was unconnected with their ulcers On this basis the incidence of duodenal ulcer in York and in Leeds was surprisingly comparable, but gastric ulcer seemed appreciably less common in York—findings which confirm the regional necropsy survey made in 1956[4] When the annual risk of developing duodenal ulcer was computed, it again appeared that men living in the city of York were more prone to ulcer than Londoners, the risk being 2 58 per 1000 in York[1] and 2 07 per 1000 in London[7] The regional differences in ulcer frequency and natural history are at present unexplained

When ulcer frequencies in town and country were compared by PULVERTAFT[1] interesting differences emerged

> Thus, ulcers were significantly more common in townsmen than in countrymen frequencies per 1000 population for duodenal ulcer were 2 40 and 1 42, and for gastric ulcer 0 62 and 0 27 respectively (the possibility that differences might have been due to varying age-distribution of the population was excluded) That the differences were in all probability real was further suggested by the fact that acute perforations occurred more commonly in town than in country in a ratio of 1 7 1 There was evidence that the differences observed were disappearing with increasing urbanisation of the rural areas, for duodenal ulcer was twice as common in town as in country in 1952 and only 1 3 times as common in 1956
>
> It was surprising that no statistically significant changes could be demonstrated in women ulcers were only slightly more common in women living in town than in the country (duodenal ulcer 1 2 1, gastric ulcer 1 5 1) This disparity was not altered after appropriate correction for the age-distribution of the population at risk.

Variations in ulcer occurrence between town and country could not therefore be explained by differences in age-distribution or social class or by the allegedly increased tempo of town life York is a quiet cathedral town with good living conditions and it is not highly industrialised It was possible that the more ambitious ulcer-prone subject might have migrated from country to town, but this could not wholly explain the changes recorded In an attempt to explain the variations, PULVERTAFT[15] investigated the smoking and, to a limited extent, the dietary habits of his urban and rural populations Ulcer subjects were compared with a matched control population attending for radiological examinations at York hospitals, subjects with dyspepsia or bronchial neoplasm being excluded DOLL et al[16] found that there were significantly fewer non-smokers amongst ulcer subjects than among matched control patients of both sexes, and that gastric ulcers healed more rapidly and completely in patients who had stopped smoking The York survey confirmed that a higher proportion of ulcer subjects smoked than did control patients both in town (84 3% to 77 8%) and in country (81 6% to 77 7%) Differences observed were barely significant, however, and the proportions of smokers in town and country were almost identical, suggesting that varying smoking habits between town and country people could not explain the differences reported Food habits proved even more difficult to investigate, but a simple preliminary survey based on the amount of sugar added to everyday beverages suggested that towndwellers consumed more sweet and sugary foods than did countrymen It was also shown that ulcer subjects, both in town and country, ate more sweet food than did control subjects of similar sex and age Whether this interesting observation has a bearing on ulcer causation in general or whether it might explain regional differences in ulcer occurrence is uncertain, but the subject is being further investigated in York and seems to open up a new path for research into this perplexing problem

Annotations

ACROPARÆSTHESIÆ AND THE CARPAL-TUNNEL SYNDROME

SINCE compression of the median nerve in the carpal-tunnel was described by Brain, Wright, and Wilkinson[1] in 1947, light has been thrown upon its nature by observations on the association of this syndrome with pathological conditions, such as acromegaly[2] and myxœdema,[3] in which the connective tissues swell, and attention has recently been directed to its occurrence in pregnancy In a paper in this issue Dr Marcia Wilkinson reports fourteen cases in which compression of the median nerve developed during pregnancy, and suggests that trauma, weight increase, and hormonal relaxation of the transverse carpal ligament may all play a part in its pathogenesis Her further observation that half her patients also showed evidence of compression of one or more cervical nerve-roots is of interest for several reasons Some, though not all, of these patients showed radiographic evidence of cervical spondylosis It seems probable that in pregnancy the physiological changes responsible for precipitating the carpal-tunnel syndrome may also produce symptoms by disturbing the normal anatomical relations of the roots of the brachial plexus, and that pressure on the nerve-roots is likelier if there is pre-existing narrowing of the intervertebral discs and foramina in the neck But the association of cervical spondylosis with the carpal-tunnel syndrome is not uncommon apart from pregnancy, and often provides a difficult diagnostic problem Is this association merely fortuitous, and due to the fact that both disorders are common in middle age and later, or, as Russell[4] suggests, does a sensory nerve react as a whole to trauma so that a lesion in one situation makes it, as it were, irritable in another?

A further point which emerges from Dr Wilkinson's observations, and from Russell's view if it is soundly based, is the undesirability of regarding acroparæsthesiæ as a symptom of a lesion in one particular situation, and of treating this symptom as though it were a disease. Before either the carpal-tunnel syndrome or cervical spondylosis was discovered, acroparæsthesiæ were usually ascribed to some disorder at the thoracic inlet, and Walshe[5] included "acroparæsthesia" among the subtitles of an article entitled "nervous and vascular pressure syndromes of the thoracic inlet and cervico-axillary canal." He also thought that pregnancy played a part in producing acroparæsthesiæ in the thoracic-inlet syndrome.[6] Later the view that compression of the median nerve in the carpal tunnel was the main, if not the sole, cause of acroparæsthesiæ, gained ground, and the symptom then came to be regarded as an indication for surgical division of the transverse carpal ligament. But there is no doubt that the radicular symptoms of cervical spondylosis include acroparæsthesiæ, which, as in the carpal-tunnel syndrome, may come on during the night. By the time that wasting of the outer thenar muscles has developed, the diagnosis of median-nerve compression is easy, but when the symptoms are purely sensory it may be difficult, in the presence of cervical spondylosis, to decide whether acroparæsthesiæ involving the radial digits are due to median-nerve compression or to a lesion of the 6th and 7th cervical nerves, or possibly both. In such cases measurement of the conduction time in the distal part of the median nerve may be a valuable aid to diagnosis.

Acroparæsthesiæ, then, are no more a nosological entity than headache, but a symptom, which may indicate disturbed function of the sensory nerves supplying the hand at one of three points in their course—the intervertebral foramina, the costoclavicular region, or the carpal tunnel. Before rational treatment can be begun both the site and the nature of the lesion must be determined.

Dr Foster's paper in this issue, describing the improvement in the carpal-tunnel syndrome produced by injection of hydrocortisone, is further evidence of the part played by œdema in the production of symptoms. The high relapse-rate he reports suggests that his treatment was not removing the cause of the syndrome. Moreover, he was dealing with early cases—two-thirds of his patients showed no abnormal physical signs. It seems, therefore, that surgery is still the treatment of choice for those patients whose disorder is not naturally reversible, as in pregnancy, and has reached the stage of objective damage to the nerve.

SALMONELLÆ IN IMPORTED MEAT

MEAT and especially "meat products" are responsible for more salmonella infections in man than all other kinds of food together. This has been clear in every annual report on food-poisoning issued by the Public Health Laboratory Service, but the reason has been obscure. In this country salmonella infections rank low in importance among the diseases of the larger domestic animals. (Admittedly, many are never reported, but the notifications of human disease are likewise incomplete.) Few animals with obvious salmonella infections reach the slaughterhouse. Attempts by bacteriologists to detect inapparent infections in home-grown carcasses have given very varied results at different times and places, but in general it would be surprising if 1% of these were infected. A recent paper on the bacteriology of imported meat may help to explain this anomaly.[1] The material was of two kinds—chilled carcasses and frozen boneless beef, veal, and mutton. Of 304 samples of the former 3.4% contained *Salmonella* spp.; of 890 samples of the latter, 10.3%. If these figures are broken down into the countries of origin they are even more striking: 18% of samples of boneless veal from country A were found to be infected. From country B both boneless and carcass meat gave figures of 7.5%. Because some of these samples were very small, it would be unwise to read too much into the figures, but beyond doubt quite a lot of infected meat is coming into this country. Incidentally about the same proportion of samples harboured heat-resistant strains of *Clostridium welchii*: without comparable figures from other sources this may mean something—or nothing.

Fourteen species of salmonella were isolated. *S. typhi-murium* was the commonest, and the rest—including one strain of *S. paratyphi B*—represented a fair selection of the species which most often cause food-poisoning in western Europe. What is interesting is that, except for the ubiquitous *S. typhi-murium*, the species found in beef and veal were not those most often associated with bovine disease. *S. dublin*, by far the commonest cause of salmonella infection in cattle in this country, was never isolated. The species in carcass meat have all been found in living cattle (though rarely), but some of those in the boneless meat have never been found in cattle at all. We are admittedly very ignorant of the distribution of *Salmonella* spp. in Nature, but these findings almost suggest that the organisms in this meat were not derived from the living animals but from some extraneous source. None of the exotic species of salmonella recently detected in feeding-stuffs were isolated from this meat.

The authors of this paper are not in a position to tell us about the conditions of slaughter of these imported carcasses or the methods of preparing the boneless meat. Experience shows that one contaminated knife may spread infection far and wide in a butcher's shop. Until more is known of this, it would be idle to speculate upon possible sources of infection of the living animal. Information on this subject is hard to obtain at home, but some Continental countries take meat inspection more seriously than we do. It would be of great benefit if the veterinary profession were to make a really extensive survey of the infection of carcass meat with salmonellæ—say at six large abattoirs over at least two years.

The dangers of this infected meat are obvious, but we doubt whether a cut off the joint is a common source of human infection. As a nation we prefer our meat sterilised. The danger lies mostly in the use of infected meat for making sausages and such savoury delights. Few cooks do more than warm the outside of a sausage, and travellers say that in some backward parts of England sausages are eaten raw. It is astonishing, indeed, that infections are so few, but most of us are probably resistant to all but an astronomical dose of all salmonellæ except *S. typhi*. Protection must be through a change in the composition of sausages or in the national eating habits—and it is hard to guess which is the less likely. Plainly the importation of this infected meat should be prevented so far as possible: the Imported Meat Regulations (1937 and 1948) may or may not apply—a question that can probably be settled only in the courts. Sterilisation by gamma irradiation has been suggested as a remedy, and though this method is still in the stage of experiment it ought to be considered seriously. Indeed the whole problem of imported salmonellæ—in meat, poultry, eggs, and offals—has now reached a point when it deserves the attention of the Ministry of Health and the Board of Trade. Unfortunately, in spite of the enthusiasm of the bacteriologists, it is difficult to be sure whether more than a very few human infections are derived from these sources.

CLINICAL RADIOLOGY AND HÆMOPHILIC BONES

THE *Journal of the Faculty of Radiologists* has been renamed *Clinical Radiology*, and important changes have been made in its format. The policy of the editorial board remains "the publication of scientific papers of interest to diagnostic radiologists and to radiotherapeutists with the main emphasis on clinical radiology." But papers on experimental and similar work with clinical implications will be welcomed, and the first number[1] includes a paper on metabolism of radioactive materials in the human body by Prof. W. V. Mayneord, and one on marrow transplantation after radiation by Dr. K. A. Porter. It also includes a most interesting article on bone and joint changes in hæmophilia and Christmas disease, by Dr. J. H. Middlemiss, of Bristol, which is illustrated by many excellent and unusual radiographs.

One of the commonest manifestations of hæmophilia is hæmarthroses. The bleeding into a joint is often repeated, the same joint being involved on several occasions; this causes damage to the structures in the joint and curious and characteristic lesions in the bones, especially in the epiphyses.

The joints most usually affected are the knees, ankles, and elbows; hip-joints and shoulder-joints are less commonly involved. Repeated hæmarthroses can eventually cause much deformity and serious limitation of mobility, and they account for the presence of so many hæmophiliacs in homes for cripples. The synovial cartilage is slowly destroyed, so the joint space becomes steadily smaller; so-called cysts, sometimes multiple, appear subarticularly below the bone surface. In children the intense periarticular hyperæmia associated with recurrent repair processes causes accelerated growth, and exceptionally large epiphyses may be formed. When the patient grows up unusually large bone ends may be formed in joints that have been involved in repeated hæmarthroses, and Dr. Middlemiss has a striking radiograph showing how one femoral head has become larger than the other from this cause.

Illustrations show other ways in which radiology can help in hæmophilia. For example, intermittent small-bowel obstruction develops sometimes in hæmophilic children, and a plain film of the abdomen shows such a case due to intussusception. A retroperitoneal hæmatoma in the right iliac fossa gives rise to symptoms and signs that closely mimic those of acute appendicitis. Operations are still to be avoided whenever possible in hæmophilia, and Dr. Middlemiss reproduces plates showing firstly the obliteration of normal landmarks on the right side of the abdomen with displacement of the bowel shadows to the left, and secondly an excretion urogram with the right ureter displaced medially by the retroperitoneal hæmatoma. In such a case laparotomy is unnecessary. Another odd condition may be found (usually in the iliac bones): repeated subperiosteal hæmatomas cause atrophy of the underlying bone, and eventually a large area is destroyed; some new bone may be formed in the hæmatoma mass. This "pseudo-tumour" gives a very characteristic radiographic picture, which again is very well illustrated. This paper should be consulted by all interested in hæmophilia and in joint disease. It and its companions in the first issue of *Clinical Radiology* set a high standard.

CELLULAR ORIGIN OF RHEUMATOID FACTOR

THE great majority of patients with rheumatoid arthritis have in their plasma a factor capable of agglutinating diverse particles coated with γ-globulin.[1] Various refinements of the original test have increased its sensitivity, and a positive reaction is now obtained in nearly all patients with the disease. The site of origin of this factor, its relationship to a true antibody, and the nature of the γ-globulin with which it reacts are still somewhat obscure.

The origin of the rheumatoid factor has been fruitfully studied by Mellors and his colleagues,[2] who applied Coons' fluorescent-antibody method. It had already been established that human γ-globulin heated to 62°C for ten minutes reacted specifically with the rheumatoid factor.[3] A histochemical reagent for detecting the factor was therefore prepared by the heat-aggregation of γ-globulin after it had been conjugated with fluorescein isothiocyanate. Sections of fresh frozen tissue treated with this reagent should, when viewed with ultraviolet light, show by an applegreen fluorescence the histological sites of distribution of the rheumatoid factor. With this reagent tissues from 10 patients with rheumatoid arthritis were studied. A control group of 22 patients without rheumatoid arthritis included many with other forms of chronic arthritis such as traumatic and degenerative osteoarthritis and tuberculous synovitis. The tissues studied included synovial membrane, lymph-nodes, subcutaneous nodules, skin, and muscle. The results were quite unequivocal. The rheumatoid factor was found exclusively in the tissues of the rheumatoid patients and was identified in only two cell types—plasma cells and the reticulum cells of the germinal centres of some lymph follicles. In the synovial membrane the positive cells constituted a small minority of the plasma cells present, while in the affected follicles all the reticulum cells were stained, but these follicles constituted only about 10% of those present. Positively stained plasma cells were also present in the affected lymph-nodes but were restricted almost entirely to the medullary cords.

Since the rheumatoid factor belongs to the group of γ-globulins with a sedimentation coefficient of 19S, confirmation of the above results was sought by using a fluorescent rabbit antibody specific for this fraction of human serum. The cells stained by this reagent always included those stained by the fluorescent-aggregated γ-globulin. It was not confined to these, of course, because not all 19S globulins have the specificity of rheumatoid factor.

The results do not prove that the rheumatoid factor is an antibody. True, the factor is apparently formed by cells now widely accepted as responsible for the synthesis of circulating antibody, but, as Mellors points out, these cells can synthesise non-antibody protein—for example, in multiple myelomas. Nevertheless the distribution of the factor is exactly what would be expected were it indeed an antibody.

As regards the nature of the γ-globulin with which the factor reacts it is difficult at present to decide between two hypotheses the first accepts the reactant as normal γ-globulin with a sedimentation coefficient of 7S,[4] and there is convincing evidence that in vivo the rheumatoid factor exists as a complex between several molecules of 7S globulin and a molecule of 19S globulin On this view the precipitation of the factor with aggregates of 7S globulin is due entirely to the more ready precipitability of the large molecular aggregates According to the second hypothesis the aggregation of the reactant molecules is of secondary importance, the primary necessity for the reaction being some change in shape of the molecules brought about by heat or by their adsorption on to various surfaces [5] Unless there is some change of this sort, it is difficult to understand why, for example, the 19S rheumatoid factor should exchange its associated normal 7S globulins for those on a latex particle or a sensitised red blood-cell

GOODBYE TO "METABOLIC INSUFFICIENCY"

THE syndrome of " metabolic insufficiency " or " non-myxœdematous hypometabolism " [6] has been defined [7–11] as a condition in which such symptoms as fatigue, weakness, and nervousness are associated with a low basal metabolic rate, normal serum-protein-bound iodine, and normal uptake of radio-iodine by the thyroid gland Patients with this syndrome are said to respond well to triiodothyronine, but not to thyroxine or thyroid extract, and a peripheral defect in ability to respond to thyroxine has been postulated We have previously expressed scepticism about the existence of this syndrome,[6] together with some concern at the possibilities its supposed existence offers for commercial exploitation We suggested that the crucial issue was whether these patients really responded to triiodothyronine but not to thyroxine, and that the only satisfactory way of deciding this was by a properly conducted " double-blind " trial

This suggestion has now been acted on by M E Levin,[12] of St Louis, Missouri 22 patients were identified by the criteria listed above (these were all that could be found in a year's study of 2290 medical outpatients) Detailed studies were made on 6 patients with the syndrome Each received thyroxine (0 3 mg daily), or triiodothyronine (0 075 mg daily), or an equivalent number of lactose tablets, in random sequence for periods of a month All tablets appeared identical, and the investigator did not know which medication the patient was receiving The final statistical analysis showed no significant differences in the frequency with which symptoms were relieved by the three types of tablet

In this group of patients neither thyroid hormone caused any greater subjective improvement than lactose tablets, and triiodothyronine was in no way superior to an equivalent dose of thyroxine The symptoms therefore cannot be attributed to any form of hypothyroidism, or to irresponsiveness to thyroxine Since Levin also showed by psychometric tests that these patients had abnormal personality patterns, it seems likely that their symptoms were essentially psychogenic This careful trial provides the first objective evidence about " metabolic insufficiency " Since the results were entirely negative it reinforces the doubts we previously entertained about the existence of this syndrome We hope that " metabolic insufficiency " will quietly disappear from medical literature

INSTITUTIONAL POPULATIONS

OUR institutions serve a variety of purposes, and the people in them are a mixed company with little in common save that they have all been deprived of something—children of the care and support of their parents, old people of the strength and activity which gave them independence, patients of mental or physical health, and prisoners of their liberty Though institutions are an essential part of our social service we are beginning to realise that they should be used sparingly Wherever possible, children should be found foster families, old people should be supported in their own homes, mental patients should be looked after in the community, young delinquents should be put on probation On the other hand practical difficulties—small families, cramped housing, women with jobs, complex medical procedures—balance this theoretical shift of social care from the institution to the community, and information about the use that is in fact being made of our institutions today would be a helpful guide to planning the social services of tomorrow Dr Brian Abel-Smith and Mr Robert Pinker [1] offer some pointers about this in their comparison of institutional populations in 1911 and 1951

Though changes in administrative procedure and in official classifications naturally preclude an exact comparison, they have been able to reach some broad conclusions which are of interest They have divided institutional populations into the physically ill, the mentally ill, welfare cases, and lawbreakers Between 1911 and 1951 the physically ill appear to have increased by 21% and the mentally ill by 26% more than would be expected from demographic changes alone, which suggests that despite the expanding domiciliary services there has been no decline in the proportion of people looked after in hospitals On the other hand the proportion of the population looked after in welfare institutions (in which they include homes for children, cripples, blind, deaf and dumb, epileptics, and the aged and infirm) fell by nearly 51% The confinement of lawbreakers increased by 36%

Analysis of the figures according to sex, age, and civil state was also complicated by changes in procedure and terminology But there has been a clear decline in the age of offenders Again, among the mentally ill the proportion of single people in insitutions doubled between 1911 and 1951 for both sexes The increase was greatest among those under 45, but this may be partly due to people in the workhouses of 1911 who would today be classified as mental defectives The proportion of people over 65, making a similar allowance for the workhouse population, decreased between 1911 and 1951 Among the welfare cases there seems to have been unhappily a considerable increase in the proportion of children and an unexpected but welcome decrease in the proportion of the aged, particularly men, in institutional care

Dr Abel-Smith and Mr Pinker emphasise that their study makes no claim to measure social needs or physical or mental morbidity, but they believe that at the very least their conclusions " do not support theories of increasing family neglect or of a trend towards ' medicated survival ' "

EUROPE'S REFUGEES IN 1960

A Lancet Survey

The World Refugee Year was launched last June in accordance with a resolution by the General Assembly of the United Nations, which named the aims as (1) to encourage interest in refugees and to secure additional financial contributions, and (2) to provide additional opportunities for permanent solutions, through voluntary repatriation, resettlement, or integration In the United Kingdom a central committee was set up, with the following objectives to aid the 160,000 unsettled refugees in Europe who came under the mandate of the United Nations High Commissioner for Refugees, to promote settlement of the 8000 European refugees on the mainland of China, to aid the Chinese refugees, numbering close on a million, in Hong Kong, and to aid the million refugees (nearly all Arabs) from Palestine

This account of refugees in Europe is based on the observations and inquiries of a member of our staff in Italy, Austria, and Germany

THE BACKGROUND

It is all too easy to think and speak of refugees either, on the one hand, as units to be added to a statistical table or, on the other hand, in terms of emotional anecdote In fact the refugee is an ordinary person in an extraordinary position his need, like that of the next-door neighbour in trouble with his bank overdraft, is for informed and dispassionate advice and well-directed help Each new refugee is an emergency, for the longer he is denied a full productive place in society, the harder will it be for him to take such a place—and incidentally the heavier will be the charge on those who sustain him in unwilling idleness

In Europe, as elsewhere, the refugee situation is never static a refugee may return to his own country, settle where he has first sought asylum, emigrate, or even move illegally to a second country where he believes the prospects to be brighter And all the time some countries—notably Italy and Austria—are receiving new refugees Consequently, no estimate of numbers is ever up to date

Last autumn, according to the office of the United Nations High Commissioner for Refugees (U N H C R),[1] Germany, Austria, Italy, Greece, and France had 110,000 refugees (including 22,000 in camps), compared with 160,000 (including 40,000 in camps) a year earlier, and this reduction was achieved despite an influx of 6000 new refugees during the year

These totals, however, include only those who satisfy the exacting U N definition of a refugee—namely, one who has been driven from his country by political or other persecution or by fear of such persecution The definition excludes the migrant who belongs ethnically to the country in which he seeks asylum (such as Pakistanis and Indians who were the victims of a new demarcation line, and the Vietnamese and Koreans who moved to the south of their countries during and after wars) It also excludes " economic " refugees who migrate in search of work. Thus the total of unsettled immigrants in Europe is far greater than 110,000, those who do not fall within the U N H C R 's definition are in danger of being returned to their own country, and are anyhow at a material disadvantage

Owing to differences in the interpretation of " refugee " and the narrow U N H C R definition, the totals shown by the Government, by U N H C R , and by the Intergovernmental Committee for European Migration (I C E M)[2] are widely discrepant

The immediate help and the eventual solutions offered to the refugee differ distinctly between one country and another Whether the refugee is encouraged to stay or to move on depends partly on the economy of the recipient country Thus neither Greece (where refugees are relatively few) nor Italy (where they are much more numerous) is interested in refugees as a source of labour Indeed, Italy has 2 million unemployed or underemployed of her own and no fewer than 400,000 of her citizens in camps up and down the country[3], and a steady stream of Italians moves out of the country to more prosperous areas, including the German Federal Republic Germany, by contrast, with her bustling economy has an economic interest in retaining all who are fit to work (Likewise, she is politically interested in retaining the 12 million of her nationals from East Germany as a lever in her efforts to secure reunification These 12 million do not rank as refugees under the U N H C R 's definition) Austria occupies a middle position Though her unemployment figure is fairly high, especially in winter, she may wish to add to her labour force in order to hasten industrialisation of the relatively undeveloped eastern region, but she is anxious not to swamp her own small population of 7½ million with foreign nationals

Such considerations, however, are certainly not in the foreground in Italy and Austria, which, at great cost to themselves, have (like Germany) steadfastly kept the door open to all proved refugees and have, it may be thought, treated the " economic " refugees not ungenerously

A recent brief visit to Italy, Austria, and Germany left three main impressions first, that refugees should be accepted as an international responsibility, the cost at present falling far too heavily on a few countries, secondly, that with effort and good will the tragic situation of the " old " refugees[4] can be transformed, and thirdly, that the machinery for dealing with refugees, which has been built up piecemeal over the years, is unworthy either of those who operate it or of those for whom it is operated

The following account is devoted chiefly to Austria because (though the numbers are admittedly smaller than in Germany) great progress has been made towards securing integration or emigration for all, and because the emphasis is not mainly on emigration (as in Italy) or mainly on integration (as in Germany) but on both together

---

[1] The office of the U N H C R , the successor of the International Refugee Organisation, is financed by direct contributions from Governments Its main concerns are to protect the interests of refugees falling within the U N H C R definition, and to help to provide for their settlement or emigration, but U N H C R is itself non-operational

[2] I C E M was created in Brussels in December, 1951, to help to restore the equilibrium between the overpopulated and the underpopulated nations through orderly migration of Europeans who could not emigrate without international assistance Under its aegis nearly a million emigrants (45% of them refugees) have left Europe I C E M has close ties with, but is distinct from, the United Nations At present 29 countries are members Strangely the United Kingdom is not a member—a defect which it is believed will soon be repaired

[3] These Italians are from the former Italian islands in Greece, from Egypt, from Tunis, from former Italian colonies, and from territory ceded to Yugoslavia

[4] " Old " in this context denotes, in the case of Hungarians, those who sought asylum before Oct 23, 1956, and, in the case of other nationals, those who sought asylum before the beginning of 1956

AUSTRIA

NEW REFUGEES

About 300 people a month cross the border illegally from Yugoslavia

Each is interviewed by the police, who decide whether he shall be graded as a political refugee The decision is conveyed to the representative in Austria of the U N H C R, who may make representations on the decision If no agreement is reached, a joint meeting is held, but naturally the final decision rests with the Austrian Government

Since last September those seeking asylum have been sent to a central reception centre in Traiskirchen, where their applications are investigated Only a very few are returned to the border all others either remain in Austria or seek to emigrate

On entry to the country the refugee registers with I C E M and a voluntary agency,[5] to which he looks for counsel and help in arranging emigration or settlement, for supplementary food and clothes and money, and for moral support If he wants to settle in Austria he may seek grants from his agency, U N H C R, and the United States Escapee Programme (U S E P),[6] and apply to the *Arbeitsamt* for work If he wishes to emigrate he may have to wait for two years

Of the "*new*" *Yugoslavs* (i e, those who have entered Austria since the end of 1955) the majority (rather over 60%) are single men aged 18–40, about 15% are single women, 12% family units, 6% childless couples, 2% over the age of 60, and 0 5% unaccompanied youths under the age of 18 Of the 2100 unsettled Yugoslavs in the country in January, all but 100 had declared that they wished to emigrate

There is an interesting contrast between these "new" Yugoslavs and the remaining "*new*" *Hungarians* (i e, those who entered Austria in 1956) Of this second group family units account for over 40%, single men for 25%, childless couples for 20%, single women for 10%, and unaccompanied youths or elderly people for the rest Moreover, of the 10,000 remaining unsettled Hungarians, no fewer than 7000 say that they want to stay in Austria Many of these could have emigrated, but they chose to remain, partly perhaps because they feel at home in Austria, which was formerly linked with their country in the Austro-Hungarian Empire, but mostly because they believe that here better than elsewhere they can keep in touch with relatives across the border

NEW AND OLD

The task of establishing the number and whereabouts of all refugees in the country is enough to make a statistician blench

On Jan 1 of this year there were 56,526 refugees in Austria under the U N H C R mandate Of this total, 6442 were living in camps and institutions under the federal administration, and 1186 were accommodated in homes or institutions owned by the various voluntary agencies, 1267 were in unofficial camps The remainder (47,631) were living in private accommodation, and, of these, about 17,000 were unsettled In addition there are about 270,000 one-time refugees who have taken Austrian nationality, including 10,000 living in camps administered by the federal authorities These people belong to one of eleven or twelve nationalities, with Yugoslav and Hungarian predominating 26,000 have registered with I C E M

ARRANGEMENTS BY GOVERNMENT, U N H C R, AND AGENCIES

Accommodation

The 137 unofficial camps contain only "old" refugees (40% ethnic Germans or Austrians and 60% foreign-speaking) These camps, of which some are privately owned, some belong to local authorities, and some are accidental aggregations, are (judging by the few seen) mostly pathetic shambles—dilapidated wooden shacks without semblance of satisfying primitive requirements The 42 official camps, run by the Government, are better often wooden Army huts, weatherproof and with more or less reasonable sanitation, but without protection from

---

[5] Some of these agencies are religious and others are "national" organisations ("national" here meaning of the refugees' nationalities) The national agencies seem likely to dwindle or disappear This is perhaps regrettable as a refugee may be dealt with more understandingly by one of his own nationality On the other hand, some of the national agencies are not interested in securing integration, even though this may seem the most suitable solution All agencies draw by far the greater part of their funds from voluntary contributions, but U N H C R subscribes to the cost of their social workers and counsellors Shortage of such workers is seriously impeding the work of most agencies

[6] U S E P was established in 1952 to aid in the reception, care and maintenance, and resettlement of escapees from the Iron Curtain area of Europe and Asia This assistance, provided through voluntary agencies working under contract, is supplementary to that offered by international organisations The programme is administered by the Office of Refugee and Migration Affairs, Department of State

the noise of children next door or from the unwelcome visitor who calls at the front door which is also the bedroom door

The Government aims to close all official camps by the end of 1962, rehousing those who do not emigrate in flats —which in some cases are being built on the site of the camp 4000 flats are going up under a joint U N H C R and Government scheme, each contributing, on average, 50% of the cost These flats are excellent—spacious and well found But the provision of a new home does not in itself solve any problem A family which for years has been accustomed to the " security " of camp life needs strenuous preparation for the responsibilities of a home, and, having moved in, it will still need wise counselling, especially as there is little enough money for the unexpectedly heavy expenses unless the family includes a breadwinner

This is not the fault of the Austrian Government which, with singular openhandedness, treats all refugees, with regard to financial and social benefits, as if they were Austrian citizens

Under the social welfare scheme an unemployed single man receives 360 Austrian shillings a month (there are about 72 Austrian shillings to the pound sterling) A married man receives 560 Austrian shillings, plus 180 shillings for each child, per month. In official camps an unemployed man pays nothing An employed man pays 35 Austrian shillings a month for rent and 8–9 shillings a day for food. In a flat he pays likewise 35 shillings a month, and the difference between this and the 100 shillings which is the economic rent is contributed by the Government. Because the U N H C R contribution to the building cost is interest-free, the economic rent is somewhat lower than it would ordinarily be Moreover, experience and standardisation are enabling the authorities to erect four flats for the cost of three earlier ones

The restricted U N definition of " refugee " has given rise to difficulty The Austrian Government relaxed its naturalisation laws to enable some ethnic Austrians to become nationals of the country These people then automatically lost the chance of obtaining a flat under the joint U N H C R -Government scheme. Accordingly, the Government has instituted a parallel scheme to build flats wholly at its own expense, but this is grinding to a halt for lack of money Political pressure against this scheme is strong, as these " new " Austrians are commonly still regarded as foreigners who should receive no preferential treatment They seem to have had the worst of both worlds

Medical Care and Health

Hospital and other medical care is provided by the Government for refugees, in or out of camps, on the same terms as for Austrian citizens The Government has set up a special home for unmarried mothers and their children

A special sanatorium—which has a high reputation—exists for refugees, but fewer than 30 active cases of pulmonary tuberculosis are known to the authorities In 1957 I C E M X-rayed on 70 x 70 mm film the 18,000 remaining Hungarians, and found active or arrested tuberculosis in about 2 5% Positive findings were reported to the local chest clinic and to the Ministry of the Interior In 1958 I C E M initiated a similar survey of " new " Yugoslavs Unfortunately this survey was terminated owing to lack of funds, but in the 400-500 cases examined the rate was again about 2 5%

Disorders that seem to be especially prevalent include " weakness of the heart " (in most cases the symptoms are those of effort syndrome), hypertension, dyspepsia (possibly occasioned in some by unfamiliar food), and rheumatism

EMIGRATION

Both Canada and Australia have in Austria permanent missions which select healthy and socially acceptable individuals and families for emigration under mass schemes The age-limit is 45, or exceptionally 50 when family units are being selected Close on 6000 emigrated in this way last year[7]

At present, of I C E M 's case-load of 26,000, some 10,000–12,000 have declared that they want to emigrate, but any such estimate is bound to be inaccurate because a person who has been rejected again and again for emigration under mass schemes (as many have) tends to despair and not to bother to declare his wish to leave the country Experience has repeatedly shown that many who have previously expressed no interest in emigrating seize on a firm offer when this is made under a special scheme

The medical criteria for selection under mass schemes are confidential, and neither the refugee nor I C E M is officially informed of the reason for rejection Thus a refugee may spend a year or longer presenting himself to one mission after another, and, having failed with all, still be in the dark as to the cause of his failure

Although the criteria are not published, some of those rejected could clearly be brought up to the required standard by fairly simple measures—perhaps a hernia operation or even just the provision of spectacles It is thus most important that each would-be emigrant should have at his disposal the advice of doctors who know roughly the missions' requirements and how they can be met, and who can inform those who have no hope of meeting these requirements there can surely be nothing more demoralising than to move from mission to mission, each time being denied for reasons untold

This need is well exemplified by suspected tuberculosis The doctor examining for mass emigration usually has at his command a single chest radiograph (tomography is occasionally arranged) Sometimes the doctor defers a candidate so that he may compare the findings over a period—a delay that could be avoided if each candidate were offered radiographic examination on entry to the country and the film (with the candidate's permission) were placed at the disposal of any mission, whose doctor could then compare this first film with that taken when the candidate presented himself Impartial medical advice at the outset, on the basis of the first radiograph, would spare some candidates months of wasted time and mounting anxiety

The task of the mission doctors is to select the healthy, and naturally they tend to reject or defer any person with the slightest hint of tuberculosis Last year the Australian mission in Austria examined 2045 persons and deferred or rejected 36 (about 2%) on account of the radiographic findings The total examined by the Canadian mission was 2400, of whom 113 (about 5%) were rejected on this ground Further investigation, if this were possible, might satisfy the mission doctors in at least some of these cases

THE " HARD CORE "

In Austria, as in Italy, the emigration of the young and healthy has tended to raise the proportion of the elderly and less fit I C E M 's "caseload" in Austria of 26,000 includes about 6000 elderly or medically unfit and about 4000 socially unfit These are the "hard core"—some of whom are scarcely more likely to establish themselves in their first country of asylum than in another Their efforts are watched with frustration by those who want to help In the words of one experienced worker "It takes as long to settle a single hard-core case as to organise the emigration of a thousand healthy people", while another declared that a social worker would be doing well if she organised the integration of two hard-core families in a month

---

[7] The cost is shared by I C E M , the Austrian Government, the Government of the recipient country, and in many cases U S E P

Elderly and Medically Unfit

Those rejected because they are over-age are especially difficult to settle Often they have a trade for which no local demand exists No longer resilient, they find it hard to adapt to a new language and new ways Thus a 57-year-old labourer refused the chance to emigrate under a special scheme to Norway, where materially his future would have been assured—probably because he could not bring himself to exchange the familiar *Gemutlichkeit* of Southern Europe for the more reserved mode of the North In this group are found both doctors and lawyers, who are the hardest of all to place no country wants them as such

The amount of medical unfitness is difficult to assess, but an I C E M survey of 12,000 in Austria two years ago revealed the following figures active or inactive tuberculosis, 500, mental disorder, 89, paralysis, 52, other chronic disorders, 72, partial blindness, 140, total blindness, 11, deaf and dumb, 48, amputees, 77, other physical infirmities, 386, vague and transitory disorders, 281, unclassified, 200

Socially Unfit

Austria has given a fine lead in establishing a home for unmarried mothers and their children, but otherwise only Sweden and the United Kingdom have accepted any of these The "unaccompanied" mother (whether her husband is dead, divorced from her, or still in the country of origin) is equally unlikely to be accepted, and yet, if only for the child's sake, this group should surely not be excluded

Likewise few countries have been willing to accept criminals Any person with a record of a crime, however small and however ancient, is generally debarred from emigrating A man who in a moment of heat struck an insulting relation of his former wife received a trifling sentence and thus disqualified himself from leaving Austria

Similar cases were recited in Germany Petty crimes, committed long ago and long ago deleted from the German register of crimes, prevent refugees from leaving the country Examples are blackmarketeering, collecting scrap metal without a permit, collecting cable in bombed houses, and insulting an official One worker in Germany suggested that a person with no crime recorded against him for three years should be regarded as having a clean sheet

ITALY

Italy has some 5000 refugees in seven official camps [8] and a further 15,000 who are more or less integrated in the community, though some 4500 are living at bare subsistence level and need continued help About 95% are Yugoslavs

Yugoslavs continue to cross the border into the country at the rate of 10–20 a day Their claim to refugee status is examined by a commission comprising 2 representatives of the Italian Government and 2 members of the U N H C R 's office About 65–70% are accepted as refugees, some of the remainder are returned to Yugoslavia

Nearly all who remain seek to emigrate About 90% succeed (5000 left the country last year), the great majority going to Australia, the rejected 10% remain in the country

Some emigration schemes in Southern Europe are less attractive than others Under a scheme for selection of trainee gold-miners for South Africa, the emigrant must undertake to stay at this work for at least four years, the penalty for breach of the undertaking being expulsion from the country

In Italy the refugee receives no money but is accommodated and fed by the Italian Government, at a cost of about 750 lire a day (there are about 1700 lire to the pound) According to some reports, the food in these camps is poor, but it appeared to be adequate Meat is served every day except Friday (when it is replaced by fish), and indeed there are authenticated reports of refugees in camps in the south selling their daily portion of meat to the less well-fed local people outside

Some of the camps are better than others, and that at Latina, in the Pontine Marshes, which is the "processing" centre for emigration, seems to be about as good and contented a place as any camp can be The attitude of the camp commandant largely determines the atmosphere, and in this camp the commandant is keenly interested and has done his utmost—for example, by pressing for amenities and by establishing a gaily coloured garden in the central compound—to diminish the bleakness associated with all such places

The refugee in Italy may with luck be given odd jobs in the camp, for which he is paid He is not supposed to work outside, but some in fact do find seasonal employment A refugee who has been in the country for three years may, if he finds permanent employment, secure a work permit, and he then gains all the social benefits of an Italian citizen Citizenship of the country can be secured only with difficulty and after a long time

U N H C R is running a camp-clearance scheme, for inclusion in which the main qualification is entry into the country before 1956 At the end of June, 1959, the 269 who qualified were of the following nationalities Yugoslavs (164), Russians who left their country before 1939 (25), Poles (21), Albanians (17), Bulgarians (12), Czechs (8), Hungarians (7), Russians who left their country after 1939 (5), Roumanians (4), Ukrainians (3), and Spaniard, Estonian, and Latvian (1 each)

At the end of this January 224 people qualified (two years ago the total was close on 600) Those who are not accepted by other countries U N H C R is trying to place in settlements—communities with care These settlements will never be entirely self-supporting, and will be a continuing charge on the Italian Government

MEDICAL SURVEYS

Since September, 1959, I C E M has operated a continuous survey, including chest radiography on 100 mm film, of newly arrived refugees, all of whom go through the camp at Trieste (The Trieste camp, a converted warehouse, is far less satisfactory than that at Latina)

I C E M has also lately surveyed all in-camp refugees (For technical reasons children under the age of 12 were not examined radiographically) Analysis is not yet completed, but of 4467 examined radiographically, 64 single adults and 27 members of families were found to have active or presumably active tuberculosis Positive findings were reported to the camp doctors This survey should prove of great value, because, although the camp doctors make periodic physical checks, active tuberculosis has hitherto been brought to light in many cases only when the refugees have submitted themselves for emigration

---

[8] These camps are at Trieste, Capua, Aversa, Farfa Sabina, Fraschette, St Antonio (nr Salerno), and Latina

GERMANY

If Germany has been left to the last in this report, it is certainly not because in that country refugees are fewer or their problems smaller than elsewhere According to U N H C R, on July 1, 1959, non-German refugees under the High Commissioner's mandate numbered about 11,900 in 52 official camps Most had been there for ten years or longer

In 1957 a survey by the *Akademie für Staatsmedizin* in Hamburg showed that the official camps contained about 2200 " difficult " cases (i e., refugees who were old, sick, or handicapped, and in need of permanent care)

The estimated total outside official camps last July was 190,000, of whom 28,000 were unsettled They included about 11,000 " difficult " cases Many of those outside official camps live either in unofficial camps or in other grossly unsatisfactory places, such as cellars The vast majority in official camps and elsewhere are " old " refugees

HOUSING

Apart from the " difficult " cases, the great problem is housing except perhaps in Bavaria, which has a great concentration of refugees, no reasonably fit adult should find it hard to secure some sort of work

In Munich alone, there are some 40,000 families on the " urgent " waiting-list for dwellings built by the local authority Of the 3068 dwellings completed last year, 1141 were reserved for German refugees

Between September, 1955, and the end of 1959, of a total of 1575 housing units planned under a special programme initiated by the United Nations Refugee Fund for refugees in official camps, 1154 had been completed Together with 1300 units planned under the camp-clearance scheme of U N H C R, the total is to be brought up to 2900 units U N H C R is contributing an average of 25% of the cost, with a matching contribution of 75% from the Government

Of the unofficial bodies, the Adoption Committee for Aid to Displaced Persons,[9] a non-denominational organisation, is doing outstanding work. Concentrating mainly on the " free-livers " in Bavaria, who are perhaps the worst-off of all, it is providing " key-money " to enable refugees to rent privately owned flats, with priority to those who have recovered from tuberculosis In addition it is largely financing the construction of a new home for the tuberculous who have been discharged from hospital but are not fit to take their chance in the community The Adoption Committee is the first organisation to have applied sizeable funds to the integration of those in unofficial camps, but now U N H C R is surveying the numbers and needs of those in these camps—in preparation, it is to be hoped, for action

SOCIAL BENEFITS AND MEDICAL CARE

In Germany the refugee who is unemployed or falls ill receives the same benefits as a German citizen. The great majority of refugees are employed, though the employment—especially of labourers—may be only seasonal A labourer earns up to 400 D M a month (there are about 12 Deutschmarks to the pound), and if he is living in a privately owned flat, which will cost at least 150 D M a month, he will have difficulty in making ends meet

After two or three years German nationality can be obtained Most, however, choose to remain Stateless—possibly because they hope eventually either to emigrate or to return to their homeland

In hospitals the refugee is treated on a par with a German citizen, and sometimes he is clearly better off in hospital than outside For instance, at Gauting Sanatorium, near Munich, the tuberculous can serve a two-year apprenticeship as mechanics the workshops are beautifully equipped and well staffed, and failure to gain a diploma at the end of the two years is unknown The refugee who gains such a diploma emerges as a skilled worker German sanatoria also house some middle-aged and elderly tuberculous refugees who have been there for up to ten years, the chronicity of their lesions perhaps being traceable to hardship in concentration camps or forced-labour camps, and to separation from friends and relatives and the conviction that no-one cares greatly how they fare

THE NEW REFUGEE

Those who come newly to the country as refugees are accommodated at Valka camp, near Nuremberg Originally built twenty-seven years ago for those attending Nazi Party rallies, it is in an appalling state The German authorities are alive to this, and by the end of the year it is to be closed and the remaining refugees transferred to the nearby Zirndorf camp, which is already partly built Thus the worst and the best of the German official camps are cheek by jowl

The decision as to refugee status rests with the courts, but where recognition is refused an appeal may be taken to first one higher court and then another—a process which may take up to three years It is unusual for an immigrant to be returned to his country after this time

Of the new refugees 90% are Yugoslavs Until their status is decided they are supposed not to take employment, but not uncommonly they engage in work without an official permit (so-called " black " work)

At Valka routine radiographic examination was instituted in 1950 but was later abandoned Last July it was resumed, and in order to gain full attendance the authorities have had to withhold meal tickets and pocket-money from those who fail to attend (This failure, it seems, is usually due, not to the refugee's fear of what may be found, but to his being absent and engaged on " black " work when the radiography unit visits the camp)

---

[9] 227, Edgware Road, London, W 2

EMIGRATION

According to ICEM, UNHCR refugees who left Germany for resettlement elsewhere numbered 5243 in 1955, 8982 in 1956, 6967 in 1957, 1151 in 1958, and 2199 in 1959

CAMPS IN GENERAL

“ When you’ve seen one camp, you’ve seen the lot ” The man who said this knew he was uttering a half-truth Certainly the worst camps look and sound and smell depressingly alike the bottle of liquor dropped by the alcoholic on the doorstep, the miserable dog which seems never to know where it belongs, the dark, dirty, creaking corridor, the mean rooms decorated incongruously with bright pictures from old magazines, the bunks strewn untidily with blankets, the old table (but no chairs), the acrid stench from the urinal, the sudden sound of a quarrel beyond the partition—these are the common denominators of camps at their worst Camps also have basically the same atmosphere—an atmosphere of insecurity and isolation, as of a prison without bars The visitor, wherever he turns, comes on little knots of two or three, standing or lounging on their bunks, exchanging gossip and rumours in subdued tones, and breaking off to regard the newcomer with uninquisitive wariness

Those with knowledge say that in camps the attitude is basically paranoid

This attitude does not necessarily derive wholly from the refugees’ present situation Strotzka,[10] in a close study of the Hungarian refugees, found two prevalent features First, some had crossed the border with minds occupied by wishful thinking about what they would find beyond miraculously this act was to end their difficulties Secondly, some had a guilt-feeling about leaving home, akin to that of a deserter Similar emotions may partly account for behavioural disorders in other “ new ” refugees

The severity of the paranoia seems to vary from camp to camp some camps have a much more oppressive atmosphere than others (On the whole the farther south one goes in Europe the lighter is the atmosphere—perhaps because the southern peoples are more easy-going) Obviously a main factor is the constitution of the group one composed of people who have just arrived and are soon to emigrate will have a better atmosphere than one containing people who have lived long in the camp and have no hope of a solution But other factors operate—for example, the attitude of the officials and the enthusiasm of the social and other workers

Opinion is divided on the advisability of social workers being drawn from the ranks of former refugees In some parts this is the practice, and the results seem satisfactory, the worker having insight into the refugee’s attitude On the other hand there is a risk of either over-identification with, or aggression towards, the refugees

In a camp refugees have a corporate spirit, though not necessarily a healthy one, and this is reflected in toleration of behavioural disorders among their members One cheering feature cannot fail to startle the visitor the children mostly look healthy and happy, and talk readily enough to any who engage their attention A possible reason is that, through propinquity, a closer mother-child relation is set up than is usual in more spacious surroundings Children, it has been found, recover quickly from any ill effects of camp life, and through friendships at school they educate their parents in local ways, thus adults with children become fully integrated more quickly than the childless For this reason it is especially regrettable that there are still some schools for the children of refugees only

Protracted camp life can undoubtedly leave a mark, but Dr Hans Strotzka,[11] who has long experience, insists that behavioural disorders evaporate more completely and quickly when refugees move to reasonable surroundings than when an ordinary group of people are moved from slums to new estates He finds refugees highly responsive to their environment

SOME SPECIAL SCHEMES

Besides schemes for mass emigration of the healthy, special schemes for a limited number of the less fit have been applied from time to time

Before the start of the World Refugee Year last summer, Sweden, Norway, and Denmark accepted groups in which individuals or members of families had active tuberculosis Sweden also took some of the “ post-tuberculous ”, and since 1954 it has taken more than 2300 “ hard-core ” cases Belgium, Switzerland, and Luxembourg gave refuge to a few mentally disabled patients Refugees have been accepted also by France and the Netherlands

---

[10] Strotzka, H *in* Die psychohygienische Betreuung ungarischer Neuflüchtlinge in Österreich 1956–58 (edited by H Hoff and H Strotzka), p 9 Vienna, 1958

[11] Personal communication Dr Strotzka is surveying the mental state of refugees in Europe The United Kingdom World Refugee Year Committee has guaranteed to meet the initial cost

So far in the World Refugee Year, Canada has accepted 100 families with one tuberculous member, and Sweden 50 and Norway 15 families with handicapped members The United Kingdom has arranged to admit 200 handicapped, and it is sending a mission to select more—the total this time may be considerably greater than 200, and the conditions more liberal Sweden is at present arranging to accept 50 families that include amputees or people crippled in other ways, and is provisionally arranging to accept a further 50 tuberculous families New Zealand has agreed to accept 70 handicapped families (including 20 from the European refugees in the Far East) Australia is undertaking a pilot scheme on the same lines

Some unofficial schemes, such as the Ockenden Venture, whereby children have been brought to this country, and a community plan in Sardinia, have proved highly successful

In Sardinia a community, financed in the first place largely by Mr Don Murray, a film actor, was set up for the reablement of "hard-core" people, including alcoholics The aim is to make this community self-sufficient Its members help to build their own houses, and otherwise engage in agriculture and chicken-farming Members of the Brethren Service Committee, a U S religious body, live in the community, which at present comprises 14 families the proposed total is 25 U N H C R contributes 1 million lire for each family which establishes itself—and the great majority do, only a few failing and returning to the mainland The scheme has the support of the Italian Government, which seeks to develop this formerly malarial island

THE NEXT ROUND

This report is admittedly fragmentary the scattered facts it contains resemble a few tiny slices from a large apple—the slices, however closely scrutinised, give little idea of the state of other parts of the apple, or of the size and condition of the apple as a whole Nevertheless, from such facts as have been gathered, and from instructive discussions with many people, a few conclusions can be reached

MASS EMIGRATION

The mass-emigration schemes are applied mainly in the interest of the recipient country, which rejects families containing one or more disabled members

One family could not emigrate because the wife was myopic, another because one child had unilateral vision, a third because one of two children was deaf and dumb, and a fourth because the husband's mother was blind

Such examples are readily multiplied If each country relaxed its immigration laws to the extent of accepting families with handicapped members which could be expected to support themselves, that would be one step forward The existing laws give rise to tension, uncertainty, and distress in those who must decide whether part of their family shall emigrate and the rest remain These laws are, moreover, out of date The insistence on freedom from suspicion of pulmonary tuberculosis derives from a bygone age today tuberculosis can be regarded as a curable disease

The U S A, Australia, Canada, and the United Kingdom have partly relaxed their immigration laws in order to keep families together Other countries could do likewise with little risk of trouble or expense to themselves

In the U S.A medical standards for refugees are the same as for others Exclusion of the tuberculous applies to aliens "afflicted with tuberculosis in any form" Under temporary legislation, adopted in 1957,[12] and extended in 1959,[13] this exclusion is waived for parents, spouses, and children of U S citizens or of aliens who either have been admitted for permanent residence or have received an immigrant visa, provided satisfactory arrangements are made for medical care and supervision and for the support of the handicapped person In 1961 Congress will review experience and consider further extension At the end of last year, 2511 persons with tuberculosis had been admitted under this provision Where the disease is shown to be inactive, history of tuberculosis is not a ground for exclusion The only ground for exclusion on the basis of history alone is "one or more attacks of insanity" People in excludable medical categories may be admitted under discretionary provisions for medical treatment, or may be paroled under conditions prescribed by the Attorney General The parole provision was applied to most of the Hungarian refugees who entered the U S.A in 1956–57, later legislation changed the parole status to that of permanent resident for those qualifying after at least two years in the U S.A

SPECIAL SCHEMES

In the planning and execution of special schemes for emigration the Scandinavian countries have played a leading part If, as must be hoped, these schemes are to be multiplied, the criteria for inclusion might be made less rigid

Under one scheme for the tuberculous, the conditions were that the affected person must be, not single, but a member of a family, that not more than one member of the family must be affected, and that the family must have *no* sponsor in the recipient country These three requirements excluded most applicants, the quota was not easily filled, and disappointment was caused to those who failed on one or another of the scores

The special schemes seldom cater for that promising group—the "post-tuberculous" (Sweden and the United Kingdom have accepted a few) It must seem a mad world to those—and they are many—who are rejected for mass-emigration schemes because they have a fibrosed lung lesion and for special emigration schemes because they do not have active tuberculosis

THE HARD CORE

Of those who have not hitherto been included in any emigration schemes, the ageing and aged, the "unaccompanied" mothers, and some of the so-called criminals are in special need of help and acceptance

In one or two of the first countries of asylum only manual work is to be had, and the over-40s who are unfit for this can look forward only to eking out the years until they qualify for an old people's home In at least one country such homes are wretched places, without privacy, comfort, or sympathy

The unaccompanied mothers (of whom a few have been accepted by Sweden and the United Kingdom) need help, first on the humanitarian ground that without a husband they are at a disadvantage in rearing their children, and secondly for the social reason that a new generation of Stateless people in Europe should be avoided If they became pregnant while they were unmarried refugees, that is no token of promiscuity "Having babies," said one worker, "is a camp disease"

Some "criminals" must be convinced that all hands are turned against them Who shall say that a man whose only penal record is a short sentence in 1946 for insulting a German official is necessarily unworthy of citizenship? Yet no country has wanted him

The United Kingdom, it seems, now denies entry only to habitual criminals In the U S A an alien "who is excludable because of the conviction of a misdemeanour classifiable as a petty offense by reason of the punishment actually imposed" may now be admitted[14]

---

[12] Public Law 85–316, 85th Congress, S 2792, Sept 11, 1957

[13] Public Law 86–253, 86th Congress, H R 6118, Sept 9, 1959

[14] Immigration and Nationality Act, p 25 Washington Government Printing Office, 1958

The "hard core" are not necessarily a burden on the country where they settle in Norway 95% of this group are self-supporting

ORGANISATION

In the exodus from Hungary no fewer than 85 organisations contributed to the care and movement of the refugees In Europe today the number is smaller, but it is still great enough to cause confusion and delay In Germany, particularly, the need for a central organisation was repeatedly emphasised Yet this unity is unlikely to be easily achieved because some agencies, though staffed by dedicated workers, are jealous of their independence and of the numbers in their care (the sums payable from official funds are related to these numbers) As it is, registration with two or even three different agencies is not uncommon

The unhealthy and unfruitful competition in refugee work, though possibly inevitable, might be abated by bringing together at one place and at one time all concerned with the well-being of the refugee—the representatives of international, national, and voluntary organisations

Each new refugee might be directed to a central depot, where he would be examined by an independent doctor and have his chest X-rayed If the refugee wanted to emigrate under a mass scheme but the X-ray showed evidence of changes likely to preclude this, he could be told, and, if he disbelieved what he was told, he could go to the mission doctor, in the same building, with the radiograph If he failed here and with other missions, he might be advised to seek entry into, say, Sweden, under a special scheme Deciding, instead, to stay in the first country of asylum, he would go to the representative of the labour office, in the same or a nearby building, who could tell him at once the prospects of employment in his trade The doctors, working close to the voluntary agencies, could inform the relevant agency without delay of what was needed medically to fit a refugee for work in the same country or for acceptance abroad—perhaps a pair of spectacles a prosthesis, or a fairly small operation

Such a scheme would involve no added expense beyond the cost of the refugee travelling to and from the centre By bringing together all resources at the same time, it would enable the refugee to decide in one or two days (instead of, as in some instances at present, one or two years) where he should go and what he was to do, and it would help to bring to light the "best" solution and not just "a" solution

The liaison between the medical side and the voluntary agencies seems to be particularly defective A sturdy man who was fit but had years ago had an amputation at the wrist was lately accepted under a special emigration scheme after having done not a day's work in his fifteen years as a refugee A prosthesis would almost certainly have made this long period less barren of work and hope

"Emigration processing centres" have already been established at Latina in Italy and at Salzburg in Austria Central "processing" might also usefully be applied to those who have been in the first country of asylum for some time without being integrated But any such scheme can be instituted only with the support—and perhaps at the behest—of the national Government

THE UNITED KINGDOM'S PART

The greatest immediate needs in Europe are, first, for more money and, secondly, for further skilled social workers and integration counsellors to ensure that the money is well spent

Not many declare that they wish to settle in this country The quota for 2000 fit immigrants to the United Kingdom, under a scheme started in 1953, was filled only last year Of 1467 "new" Hungarian refugees in Austria who were asked to name their country of first choice, only 17 named Britain (The favourites were the U S.A, Australia, Canada, Germany, Sweden, and South Africa, in that order) But any such list, as has been said, is misleading If the same 1467 had been told "You may go to settle in the United Kingdom on Tuesday week", many more than 17 would have eagerly accepted To the refugee abstractions mean little only specific offers bring to light what he is willing to do

As has already been mentioned, the number of handicapped admitted to this country is likely soon to be increased substantially[15] Two groups who deserve special attention are the tuberculous, and the post-tuberculous who are at present mostly barred from emigrating to Australia or Canada under mass schemes (Some, in whom the disease had been quiescent for at least two years, were admitted to the United Kingdom under the "2000" scheme, and under the "200" scheme a few patients with active tuberculosis have been selected)

The United Kingdom might offer to accept the "post-tuberculosis", and their families, on the understanding, reached with the two Commonwealth Governments, that if further investigation should confirm that the chest condition was satisfactory, or if the condition was made satisfactory by treatment, they would be accepted by one or other of these countries A few would, despite treatment, fail in the end to satisfy the requirements of these countries—a risk which would have to be made clear to the families concerned This country should surely be willing to give asylum to these few Many more would be enabled to settle in the country of their choice

Such an effort by the United Kingdom would be a small practical step towards relieving the overburdened first countries of asylum Other possible measures are discussed in a leading article on p 475 of this issue

Many have cheerfully set aside their own work for minutes, hours, or even days to supply information for this review We are especially indebted to the following

In London Monsieur René Dutilleul-Francœur, representative in the United Kingdom of U N H C R, Dr C A Boucher, senior medical officer, Ministry of Health, Dame May Curwen, chairman, and Miss M Holmes a Court, general secretary, British Council for Aid to Refugees, Mrs F C Rigby, chairman, and Mrs Erica Linton, secretary, Adoption Committee for Aid to Displaced Persons

In Geneva Dr Hans Strotzka, mental health adviser to U N H C R, Dr K G Watson, chief medical officer, I C E M

In Rome Dr E Schlatter, representative in Italy of U N H C R, Dr G B Watkins, of I C E M

In Vienna Dr Gertraud Voekel, of the Ministry of the Interior, Mr K C Elliott and Mr W K McCoy, of U N H C R

At Linz Mr Arne Torgersen, of U N H C R

In Salzburg Mr J L Carlin, Dr Cleve Schou, and Monsieur Roger Walon, of I C E M

In Munich Mr M E Ettmuller, of U N H C R, Mr Ronald Watson, of the Adoption Committee for Aid to Displaced Persons, Miss Shelagh Armitage, of the Women's Voluntary Services

At Gauting, Bavaria Dr Hubert Tuczek, medical director of the sanatorium, Frau Irmgard Neumann, chief social worker at the sanatorium

At Nuremberg the Commandant of Valka Camp, Fräulein F Scmerssner, of the U N H C R office at the camp

In Bonn Mrs S Lennox, of U N H C R

None of the errors in this account, and none of the opinions (except where these are specifically ascribed), should be associated with those named here

In England Now

A Running Commentary by Peripatetic Correspondents

AFTER addressing envelopes for several hundred reprints I have been impressed by the length of the American addresses. This is the kind of thing I have been writing most of the day:

Waldo P. Whattamouthful, Junior, M.D.,
(Director of Polysyllabics) #4231,
The Medico-Psycho-Idiopathic Centre,
Bureau of University Medical Services,
The Croesus L. Goldendough Memorial Foundation,
The University of North Jabberwocky,
1234, East 49th Parallel Street,
Jabberwocky City, 23,
State of Louis Carrolina, U.S.A.

But every now and then my cramped writing hand gets a chance to recover when I write an English address:

B. Brief, Esq., M.D.,
Barts Hospital

* * *

Here I and sorrows sit. Here is my throne, bid kings come bow to it. That was the gist of Connie's reply to our public-convenience cleaner. He is a mild inoffensive little man, with a half apologetic air, as indeed befits the duty of his calling upon both sides of the island refuge in our market square. Constance is made of sterner stuff and knows her rights down to the last pennyworth: she behaves like the dowager queen of a far-flung realm. But she will insist on spending her nights in our public convenience. We would not mind if she just curled up quietly to roost in the end cubicle: we would leave the door ajar and lay at her disposal the full range of our social service. Constance has her own ideas about community care; she has money of her own in the purse beneath her skirt, she has travelled the world and still likes England best. She must be nearly seventy and she is fond of fish and chips. The trouble is that fish and chips are wrapped in newspaper, and newspaper is as tough as Connie. If we have had to rod that drain once we must have done it twenty times.

When she came into winter quarters with us last year she was willing to live and let live, but, like the permanent residents in a guest-house, she has become over-possessive and almost proprietorial. The electric light bothers her eyes in the evening, so she climbs up and removes the bulb. Our other guests have to fumble their urgent way with matches or a torch, and then Connie puts on a deep gruff voice and startles them out of their wits with a torrent of words that are usually only written in such places. We get indignant demands for money back next day, and wild accusations about the morals of our town. Once tucked in for the night Connie will not come out. We called the police. One of our new policewomen tried chirping through the door for ten minutes, and then went back for the sergeant. He brought a scaling ladder and had the advantage of a face-to-face discussion across the cistern. Constance rested her case upon the common law of England. As one of the public, she found it a great personal convenience to enjoy in the fullest sense the unlimited value of what she had paid the proper price for. The police retired defeated and said it was our pigeon. The cleaner suggested squirting his hosepipe underneath the door, but luckily I phoned the Town Clerk first. He mumbled something about assaulting an invitee and advised against it. So Constance, flushed with success, remains our paying guest. She says she is thinking of moving at Whitsuntide to one of the seaside towns. The cost of living remains the same wherever she goes: no bother about hotel bookings. England is her realm, and she seems enthroned for life.

* * *

Down the corridor I have a neighbour who, I suspect, has lost half his colon, like me, and is enduring the rigours of cloacal rehabilitation. We share the services of a one-nurse-power 1959 model tubular-framed wheeled bedpan carrier whose reassuring presence in the room is replaced by a sense of grievous need when he wins it from me. I suppose he feels the same. The red banner permanently placed over the bedpan seems to be of historic significance, I suppose the vehicle was not covered by the Act of Parliament which replaced the famous "Red Flag Act". Incidentally no bell, siren, or hooter is fitted, all warning noises being provided by the driver. This feature is not even to be found in the annual veterans' trip from London to Brighton.

* * *

Veterinary surgeons attempting to medicate rhinoceroses meet high consumer-resistance, because their patients, though well down the list of potential passengers in lunar probes and similar rocket-propelled television sets, have lamentably little confidence in the progress of science. This unhealthy attitude of mind has been countered at the San Diego Zoo by a vet who uses a rifle and plugs the intransigent reactionaries with medicated bullets.

The reluctance of rhinoceroses to swallow strange chemicals is in awesome contrast with the habits of that Lord of Creation and Nature's Noblest Work, *Homo sapiens*, who pours such substances down his gullet like coal down a chute. If threatened with medicinal bullets, he would probably charge the guns in the manner of an ecstatic Fuzzy-wuzzy storming a British square.

Nevertheless, for the G.P., though his visiting-list makes him feel more like shooting himself than his patients, but only just, missile therapy could hold certain attractions. Sitting happily at the butts in his consulting-room, the patients would be propelled from a trap across the room and out through the front door. The really pukka practitioner would of course not fire until he could see the whites of their gluteus maximus, and unsporting habits like potting the sitting clients would be anatomically impossible.

Invitations to colleagues to come over and shoot—"Make it a Monday, easily the best day. I've 1500 brace on my list"—would be eagerly sought after. Going on safari after patients, and "sitting up" for the craftier varieties in trees under which has been tethered a 16-oz. bottle of tonic, offer interesting possibilities, and how expeditiously one could empty a crowded waiting-room by loading with every pill in the sample-drawer, hurling open the door, and administering what in Nelson's day was known as "a whiff of grape".

* * *

We were prepared to think that our children believed that all human activity centred around hospitals, just as Daddy's did, but we did not realise that the belief extended to the animal world. We were on our first holiday in Australia and walking along a red dirt road listening to the new bird songs. Suddenly we came across a large lizard lying inert in the sand with its head obviously crushed by a passing tyre. Jan, aged three, said accusingly, "That poor lizard is dead, Daddy. You must have run over him with the car." We denied this, but the inquisition continued. "Was it a Mummy lizard or a Daddy lizard?" Empirically we declare it male. "Why did he get run over, Daddy?" Here we offer some propaganda for road drill. "He could not have looked both ways before he crossed the road." "Why did he not look both ways before he crossed the road?" Desperate now—we groan, "Perhaps he was hurrying home from work." "What hospital did that lizard work at, Daddy?"

REQUIEM

Alas! Poor Spens beyond our range
To Limbo has been sent.
We swore that we would take no change
But now our Spens is Spent.

Letters to the Editor

PRIVATE PATIENTS IN THE NATIONAL SCHEME

SIR,—Your views on the subject of drugs for private patients seem strangely confused Having stated that " within the National Health Service, medical privileges cannot be bought " you add " The apparent exception—the private bed in a hospital—is not really an exception at all the patient in a pay-bed is paying at least the full cost of his treatment " Perhaps one may ask why you have omitted that other exception, the amenity bed, in which privileges are " bought " at considerably less than cost price

You aver that the doctor's time and convenience of access to him are an important part of good personal care and that *the commonest criticism of N H S general practice is that it fails to provide these things* (my italics) You then go on to state that such medical care should be " provided not sold " But surely all medical care, whether secured privately or by compulsory insurance and taxation, is " bought " and, by the same token, " sold " Following these confused imputations about buying and selling you go on to suggest that the private doctor is " selling care of a higher standard " If this be so (and if *The Lancet* is really interested in high medical standards as opposed to budgetary semantics) then surely it is to be encouraged

A lot of rubbish has been talked about *two* standards of medical care (chiefly emanating from the Socialists and echoed by the Cohen Committee) when there are manifestly many different standards both in State and private practice Good State Medicine may be better than bad private practice, but good private doctoring tends to be better than most State doctoring for good Medicine takes time and time costs money If the State is unwilling or unable to provide the G P with more money and proper incentives then any sane Government should be grateful that some patients are keen and willing to do this themselves Despite all the impediments placed in their way many patients do, to their credit, prefer to exercise some measure of personal responsibility for their medical care To help those who are thus prepared to help themselves seems both sound finance and sound philosophy

You, Sir, seem concerned that higher standards in private practice will show up some of the defects of N H S doctoring Far from this giving anyone, as you suggest, a vested interest in preserving the defects of the N H S (and defects exist in private practice too) it must surely encourage higher standards all round Certain it is that improvements in the conditions of N H S practice are more likely to come about if capitation-fee Medicine has to stand up to lively competition from private Medicine The present near-monopoly by the State is surely contrary to the best interests of British Medicine

London, W 1 REGINALD S MURLEY

SIR,—The argument that a fee-for-service system of payment is anathema to the N H S seems unreasonable It already exists for obstetrical work, domiciliary consultations, and the use of an electrocardiograph It seems a pity to reason the case from false premises

I fear " two standards of care " are already firmly built into the N H S, so long as the conscientious doctor is financially poorer by the more care and attention he gives his patients

He has the choice of being financially solvent with an uneasy medical conscience, or financially straitened with a clear medical conscience I think most doctors actually working a practice will agree with this unpalatable fact, ignored by administrators and politicians

Burley, near Ringwood,
Hampshire R HOWARD

SIR,—You rightly stress in your editorial note on last week's letters that the amenities of the ordinary list should be improved. But would you not agree that it would be reasonable for the occasional patient to pay a fee for the privilege of being seen in his own home, or under conditions of greater comfort and privacy, for any minor disorder for which he might otherwise be expected to attend the surgery?

Workington R N R GRANT

SIR,—As a private practitioner I already make use on behalf of my patients of the consultant, radiological, pathological, and other specialist services provided by the State at their expense, and my signature suffices to secure them the sick benefit, maternity grants, and so on to which they may be entitled, I cannot, therefore, follow the reasoning in your annotation of Feb 13, that to obtain their medicaments for them from the same source, and to undertake to conform with the modest standards of economy and propriety in prescribing expected of doctors in the N H S, would introduce an entirely new relationship with the latter, and involve, as you put it, *entering the Health Scheme*

Furthermore, Sir, even were you correct in crediting me with a secret desire to perpetuate " the defects of ordinary medical care ", I find it extremely difficult to conceive what practical measures I could possibly take to further this deplorable purpose If the State can find the incentives to provide within the N H S the standards *of care for which at present patients turn to private* doctors, no doubt private practice will disappear, but until that has happened, to hamper it by unfair discrimination, or to abolish it altogether, which would seem to be the logical conclusion of the views put forward in your annotation, would do nothing to encourage " a vested interest in getting rid of the defects in ordinary medical care ", but would merely destroy the yardstick by which its quality could be assessed

Richmond Green
Surrey IAN FERGUSSON

POLIOMYELITIS RISK TO EUROPEANS IN THE TROPICS

SIR,—Professor Scarborough's letter last week on the risk of paralytic poliomyelitis to visitors to Nigeria is too limited in its scope Our teaching in this hospital has always stressed the supreme importance of paralytic poliomyelitis in Europeans in tropical climates

It is generally recognised that since the introduction of proguanil (' Paludrine '), the greatest risk to which the European is exposed anywhere in the tropics is paralytic poliomyelitis There can be few of us with much experience in the tropics who have not lost friends, relations, or colleagues from that malady

The Services, the Colonial, Foreign, and Commonwealth Relations Offices have for some time past provided inoculations with subsequent booster doses for all personnel and their families in tropical countries from the exiguous supplies of vaccine available

Missions and commercial firms have been helped to the limit of our capacity in the past 2 years

Fortunately the improved supply position does away with the hitherto invidious task of refusing the vaccine to deserving travellers without a " permit " and enables all who are going to the tropics—even on a short visit—to receive this most necessary inoculation

Hospital for Tropical Diseases,
University College Hospital,
London W C 1 GEORGE R MCROBERT

AUTOTRANSFUSION IN RUPTURED ECTOPIC GESTATION

SIR,—Dr de Glanville (Feb 13) need have no fear that blood shed into the abdominal cavity from a ruptured ectopic gestation rapidly acquires poisonous properties making it unsuitable for autotransfusion In many of the cases referred to in my previous letter (Jan 2) the blood had already been shed two, three, or more days before the operation, moreover, as is well known, there are often episodes of slight bleeding over a week or more before the final heavy hæmorrhage takes place

When I stated "Naturally, only recently shed blood is suitable, the method is less applicable, but is also less necessary, when intra-abdominal bleeding has already been present for several days", I was referring to the practical difficulty of collecting *fluid* blood as distinct from blood clot.

The second part of Dr de Glanville's letter is sadly reminiscent of the fable of the Fox and the Grapes because he does not like the idea of autotransfusion (at least, after 10 hours), he takes refuge in the supposition that blood-transfusion does not matter Doubtless, there are many patients—even those seriously ill—who do recover without transfusion, but can anyone seriously contend that a pulseless, collapsed woman with two or more pints of blood free in the abdominal cavity is not, in many instances, saved by blood-transfusion, or that her convalescence is not greatly hastened by bringing her hæmoglobin back to normal levels? And in West Africa, where Dr de Glanville has worked, the patient's need may be even greater, for malnutrition, malaria, or hookworm disease may have brought her to a serious degree of anæmia before the pregnancy started

It is because autotransfusion is, curiously, so often regarded with incredulity that I feel it a duty to demonstrate the method to my students who may, in time to come, practise in regions where blood-banks are unknown I bear with fortitude their remark that, being a Scotsman, I cannot endure seeing blood wasted

The Radcliffe Infirmary,
Oxford.
J CHASSAR MOIR

COST OF DRUG TREATMENT

SIR,—I should like to comment on Dr Miller and Dr Smith's statement, in their article of Jan 2, that "rather more than three-quarters of all National Health Service prescriptions are for tablets, *the dispensing of which does not call for any high degree of professional skill*" (my italics)

It is, of course, well known that practical pharmaceutical skill has to a great extent moved away from the retailer into the factory, but this does not mean that the retail pharmacist is for ever relegated to the lowly position of a counter of "ethical" pills and tablets Far from it, because, as Sir Hugh Linstead has so rightly stated, "Here indeed is the modern role of the pharmacist to keep abreast of the new wealth that pours from our research laboratories"

The rapidly rising standard of pharmaceutical education today, with its emphasis on pharmaceutical chemistry, pharmacology, and therapeutics, is equipping the pharmacist for his true professional role—that of a recognised authority on the chemistry, actions, and uses of new drugs New medical products are becoming increasingly complex both in their chemistry and usage There will, therefore, be greater need than ever, in the years ahead, for knowledgable pharmacists in retail practice and in hospitals to make a detailed study of new drugs and to make this knowledge available to the medical profession, to help them choose the best therapeutic agent once a diagnosis has been made I am certain that there are, even today, many retail and hospital pharmacists who are living up to the highest professional standards in providing just such a service

The pharmacist of tomorrow will be even better equipped to render this service, and I feel that Dr Miller and Dr Smith are doing a great disservice to their own profession as well as to pharmacists in general by giving the impression that there is no more to pharmacy than the counting of N H S tablets Even in the dispensing of tablets the vigilant pharmacist uses a great deal of professional knowledge, for he is the last line of defence between the patient and the wrongly written prescription, of which there are perhaps more than the medical profession are prepared to admit Unfortunately one seldom hears of this important aspect of the pharmacist's work, but it is one which will undoubtedly become even more important and necessary as drugs become more and more potent and specific in their actions and hence more dangerous if prescribed or dispensed wrongly

TRIAL OF ORAL CONTRACEPTIVES

SIR,—The appeal for volunteers for a trial of oral contraceptives (the Pincus pill) in Birmingham recently has resulted in a spate of letters from doctors all over the country asking for further particulars about the pill and its use May I through your columns give an outline of the pill, the present position, and the future possibilities?

There are a number of orally active progestational steroids now available In addition to their uses in endometriosis, menorrhagia, subfertility, &c., they can be administered in such a way as to inhibit ovulation One of them, norethynodrel, has been used extensively first by Pincus and his colleagues in Puerto Rico and since then by Tyler and others

Three such compounds are being used for clinical trial in this country

'Enavid' (Searle) norethynodrel + added œstrogen	5–10 mg
'Secrosterone' (B D.H) dimethisterone	20 mg
'N E.A' (Schering) 19-norethisterone acetate	5 mg

These steroids inhibit ovulation There is an associated endometrial effect and hostility of the ovulatory cervical mucus, which may also have contraceptive value Experts are agreed that the investigations so far carried out indicate (*a*) administration of these pills for three or four years is harmless, (*b*) there is no decrease in subsequent fertility, fertility is restored to normal, or even improved, as soon as the administration is stopped, (*c*) they are not carcinogenic.

Further studies are essential to find out the long-term effects and the effects on the menopausal woman (as withdrawal bleeding takes place each treatment month, the normal amenorrhœa of the menopause is masked it is believed, however, that the menopause is not postponed and that the decrease in primordial follicles with age is not affected by administration of these steroids)

Small trials under the auspices of the Council for the Investigation of Fertility Control have been undertaken in this country in the past year The new trial launched in Birmingham is the third Very careful medical supervision with endometrial biopsies, postcoital tests, &c., where indicated, are used in these trials for research purposes

Although these steroids are harmless, a number of patients drop out because of unpleasant side-effects, notably nausea, headaches, and upset in the menstrual rhythm Close and constant medical supervision is necessary to ensure that this irregularity is dealt with in the proper way, otherwise there might be breakthrough ovulation

The pills are administered in the doses given above (though smaller doses are now being tried) daily from the 5th day of the menstrual cycle for 20 days This will normally be followed by a withdrawal bleeding If breakthrough bleeding occurs (that is, during administration) it seems best to stop and allow a withdrawal bleeding, regard it as an early menstrual period, and commence administration again on the 5th day for 20 days If menstruation is delayed beyond 8 days after the drug is finished, it must be given again as if menstrual bleeding has occurred. Very often, though there are irregularities in the first three months of administration, these settle down thereafter In the same way, nausea may be present for the first few days, but may then disappear spontaneously and completely

These difficulties, plus the present expense and the fact that the tablets must be taken regularly or bleeding occurs, or fertility may increase, mean that they are not really suitable for prescribing at present They seem to be reasonably efficient if taken faithfully Pincus' investigations gave an all-over efficiency of 70%, but he claims that only one pregnancy occurred among those women who had taken the pills exactly as directed

While the development of these steroids as oral contraceptives is a most interesting step forward in the search for simpler contraceptives, it seems at present that they are not what we are all looking for something much simpler, much less expensive, and preferably with a chemical and not a hormonal action, would be preferable if it is to be used on a large scale to deal with the enormous problem of rapidly expanding population in underdeveloped countries

May I make it clear that these trials are quite separate from the normal working of the Family Planning Association clinics Patients who attend F P A clinics will continue to receive advice on maximum safety methods of contraception

Medical Secretary, Council for the Investigation of Fertility Control
London, S W 1

WHAT IS A TRANQUILLISER?

SIR,—May I propose that we adopt the following definition of the word "tranquilliser"?

"A tranquilliser is a drug produced to compete commercially with chlorpromazine, which has no unequivocal therapeutic efficacy, which aggravates the risk of suicide by its depressant action or creates the risk of addiction by its euphoriant effect, and which, by masking the signs, tends to interfere with the recognition of early psychotic states"

Hartwood Mental Hospital,
Shotts, Lanarkshire
L N COOK

FATALITIES AND SPORT

SIR,—Dr Taylor (Feb 20) is teasing you This would doubtless be amusing were it not for the possibility that some of your readers, who perhaps have not been following the argument, might be deceived into thinking that he really means what he says

From ancient days it has been accepted by the common law of England that it is not the act itself, but the wrongful intention that prompts it, which determines whether or not blame may be laid upon the doer The law also presumes that a reasonable man must be taken to intend the natural and probable results of his actions Both these are in accordance with common sense and the usages of civilised communities

In every sport except boxing injury is accidental in the sense that it is sustained against the rules or in spite of them In boxing the avowed intention is to produce injury, and having done so, to exploit it until the injured man is effectively defeated, The London Amateur Boxing Association's recent handbook, *Medical Aspects of Amateur Boxing*, is commendably frank in this regard On p 12 it is stated without equivocation that "Injury to the cranium and its contents is a direct product of boxing and *not an accident as in all other sports*" (Italics not original) An act does not have to be unlawful before it can be recognised as totally unjustifiable

Of course a death in any sport is to be deplored But an accidental death in the course of a game of rugby football is rather a different matter from a death in the boxing ring The rules of rugby do not condone deliberate injury, the rules of boxing facilitate, and are designed to produce, deliberate injury That is why many of us think that boxing should be prohibited whilst not in any way wishing to interfere with other sports There is no inconsistency here

It is true that some people evidently find it difficult to grasp the underlying principle This places a special responsibility on us all not to create confusion in their minds on purpose

Godalming
J A WAYCOTT

SIR,—In rugby football injury is accidental In boxing it is deliberate

London, S E 5
F B BYROM

CASUALTIES AND CASUALS

SIR,—I am in complete agreement with Dr Doyne Bell (Jan 30) that casualty departments should be renamed "accident and emergency departments"

At the North Lonsdale Hospital, Barrow-in-Furness, and at Preston Royal Infirmary, the cases dealt with in the casualty departments are restricted Both hospitals contend that "consultation and treatment in this department are intended for (1) recent accidents, (2) urgent cases of collapse, &c, and patients referred from their own doctor by letter" (There are notices to this effect outside each department)

In Barrow we include under recent accidents those which occur after the general practitioners' evening surgery and who attend hospital up to 10 A M the following day If the patient has been sent by his own doctor with a condition that is not urgent, he is referred to the next appropriate outpatient clinic

Patients who do not come into the above categories are referred to their own doctor with a printed letter stating that the case is not considered an emergency Exceptions are made for patients who would suffer hardship by doing so, and for all eye cases During the day the "sorting" is carried out by the clerk in charge of the casualty records with advice from the casualty officer

The age-distribution and sources of new patients are similar to Dr Fry's series but a comparison of diagnostic classification cannot be made without breaking down his figures still further The only type of medical or surgical patients seen in the department are those who have collapsed at work or in the street, &c, because patients sent by a local practitioner are admitted directly to the wards concerned and *not* through casualty

Analysing our figures we find that 30% of casualties have wounds which require two or more sutures, 14% are limb fractures, of which half involve wrist and hand, 13% are foreign bodies in eyes, and 10% are contusions and 4% sprains 57% of new attenders arrive within 2 hours of the accident and another 14% within 24 hours

As a result of their first attendance 60% of patients were discharged, all of whom had been given a letter for their own doctor 3% did not reattend when asked to do so 7% were admitted, and the remaining 30% reattended (two-thirds of these once only) This last figure would be smaller, but a "standing order" in this hospital is that those cases *not* seen by the casualty officer himself must reattend to see him or the consultant in charge of the department Half the reattenders were referred to other outpatient departments

In support of Dr Fry our figures show that 33% of cases seen in casualty could only have been dealt with there, but 40% could have been treated by the G P and 5% by a nurse only

To save the more "regular clients" many injections of A T S and the wait thereafter, all those given A T S are recalled 6 weeks later for tetanus-toxoid immunisation The aim is to immunise the local working community and children 80% of these patients do attend for the course and since the scheme started two years ago [1] over 2000 have been immunised (more detailed figures will be published soon)

This casualty department is staffed by a casualty officer, who is also the orthopædic registrar, and in his absence, by the house staff, though he is available if required There is a consultant orthopædic surgeon in charge, who does four 1-hour sessions a week in the department reviewing certain cases, including some of the fractures

---

[1] See *Lancet*, 1958, i, 1176

General practitioners have direct access to the X-ray department, but perhaps do not use this facility to the fullest advantage Those of their patients who have fractures are automatically referred to casualty by the radiologists after they have seen the wet films As the waiting lists for outpatient appointments are not large, except in the ophthalmic department, casualty is not often used by the local doctors as a short cut to outpatient clinics

I agree entirely with Dr Fry on his views as to the future of the casualty department The number seen has increased and the main reasons are probably (*a*) there is a 24-hour service, (*b*) there seems to be a general belief amongst the public that even the most trivial injury should receive hospital attention, (*c*) the attitude " we pay for it so let us have our money's worth " Most of us who were children before the war would never have been sent to the hospital or even to our doctor with the minor trauma which today is often seen in casualty departments

Barrow-in-Furness

P A GARDNER

INFANTILE STRUCTURAL SCOLIOSIS

SIR,—Mr Denis Browne (Feb 13) criticised the incompleteness of your annotation of Jan 30 I should like to support your main point—that further knowledge of the ætiology of this condition is the most essential requirement for improvement in methods of treatment

It might perhaps have been worth mentioning that 80% of infants have a lateral curve of 10° or more at 6 months, 46% at 12 months, and 7% at 18 months, the normal stimulus of assuming the erect posture apparently being the factor leading to correction of this type of curve [1] The existence of a resolving type of structural infantile idiopathic scoliosis, as distinct from the progressive variety, was first described in a paper published in 1955 [2] Further evidence has more recently been published of resolution in older children,[3] and discovery of the cause of resolution would certainly be an important advance in our knowledge of the ætiology and treatment of idiopathic scoliosis Although Harrenstein[4] described the recovery of a limited number of very young patients with lateral curvature of the spine he, as others have done, attributed it to a form of treatment

Those interested in the subject would be grateful to Mr Denis Browne for producing any evidence that progressive infantile scoliosis can be cured in early infancy by " splinting and physiotherapy "

CATHETER DRAINAGE AND INFECTION IN ACUTE RETENTION OF URINE

SIR,—We entirely agree with Mr Harrison (Feb 20) in preferring the Gibbon catheter to the ordinary rubber and plastic catheters for bladder drainage

However, the work which we reported on Feb 6 was started before the Gibbon catheter became available, and finished more than a year ago It had as its principal object the evaluation of closed drainage in the treatment of acute retention of urine We wished to test the effect of preventing the ascent of contaminated air-bubbles in the drainage tube, uncomplicated by a change in the type of catheter used For this reason, we continued to employ the latex and plastic catheters (size 18 and 20 F) which were in routine use when we began our investigation.

In the periods of up to a week or so for which our patients were drained, urethritis was not severe enough to necessitate changing the catheters and closed drainage gave excellent results, as we have shown However, the Gibbon catheter is preferable even for short periods of drainage, and is especially preferable for longer periods We now use it routinely, but should perhaps say that the Gibbon catheter is not suitable for draining the bladder immediately after prostatectomy The narrow lumen is readily blocked by clot For postoperative drainage we now employ a boilable ' Neoplex ' catheter (size 22 F) in conjunction with the apparatus for closed drainage and irrigation which we described in 1958 [1]

ASHTON MILLER
W A GILLESPIE

ANTI-SMOKING CAMPAIGN

SIR,—Thank you for the space you gave to the interesting account (Feb 6) of the commendable anti-smoking campaign by the Edinburgh Public Health Department Such a campaign is bound to make an impact whose value cannot be immediately assessed But there are, I suggest, two lessons to be noted

First, a national habit can be adequately faced only on a national scale Edinburgh has given a noble lead But its example has been largely offset in the minds of smokers (who are, of course, on the lookout for an excuse to continue their habit!) by the lack of such a lead elsewhere As doctor after doctor has written to our Society to say, this thing demands a central lead and a national campaign All honour to Edinburgh Public Health Department for their splendid local lead! But none to the Ministry of Health for the national lead they have not given!

Secondly, we are confronted with a vicious circle—or more than one Warning boys and girls against smoking must be reinforced by parental example. But adults who are enslaved by the habit cannot give such an example Over 4000 such adults have written to our Society pleading for help to free themselves from this slavery But when they *have* managed to succeed, they are confronted with an environment in which smoking is still allowed in almost every public place, so that they find themselves almost forced to resume smoking in self-defence On top of this, of course, there are the massive advertisements and vested interests ranged against us, while the anti-smoking forces are weak and impoverished

The National Society of Non-smokers is trying to curb cancer by curbing (at every turn) what has been identified as a main factor in the increased lung-cancer mortality We are seeking to warn society, curb smoking, deter youth, protect non-smokers, free " smoke-slaves " We shall gratefully welcome the moral and financial support of new members

138, East Dulwich Grove,
London, S E 22

HUBERT V LITTLE
Secretary,
National Society of Non-smokers

SIR,—The conclusions of the Edinburgh investigation (Feb 6) are what might have been expected The position would be much the same with other drug addictions if dealt with as timidly and respectfully Would exhortations, lectures, &c , have much effect on the use of heroin, cocaine, and opium if their manufacture, advertising, and purchase were free and uncontrolled ?

It would be refreshing to see the Ministry of Health return to earlier public health traditions, when abuses were boldly dealt with Nowadays the Ministry seems to hang back if there is any question of antagonising public ignorance and apathy, or offending powerful advertising, industrial, or other vested interests

London, W 8

G G SHERRIFF

SIR,—All such campaigns go about it the wrong way The expected response of most people, especially the young, to statistics about the ill effects of smoking on health in middle life and old age will be " We, as a nation, prefer to die on our feet rather than live on our knees ” What is needed is subtle build-up of the non-smoker and smirching of the smoker statements or proof that the cigarette is a substitute for a dummy or a mummy, that smokers are neurotic, dependent individuals unable to stand on their own feet without the aid of a symbol of maternal protection, while non-smokers are strong, independent, self-reliant types I am sure such an approach would have much more success than exploitation of the fear of cancer

THE ROYAL COMMISSION'S REPORT

SIR,—Your excellent leading article last week on the report of the Royal Commission states correctly that the recommendations on pay for house-officers are higher than the recommendations suggested by the British Medical Association This is true, but to complete the story you should also mention that the Commission's *rates for house-officers are lower than those suggested* by the Medical Practitioners' Union

Originally the B M A proposed a flat 24% (later 29%) for all grades In its evidence on the remuneration of hospital medical staff submitted to the Royal Commission in April, 1958, the M P U drew attention to the plight of junior hospital medical staff and the Spens recommendation that " intending specialists should not be called upon to pass through a period of comparative penury " This was one of the factors that led the B M A to raise the amounts suggested for registrars and house-officers The M P U submitted the same figures for consultants as those suggested by the B M A , but for registrars and particularly house-officers they were higher In this respect the Royal Commission has suggested figures which are somewhere in between

I think that it can be fairly said that the Medical Practitioners' Union has done a service to the whole profession by drawing the attention of the Royal Commission to this anomaly and with very excellent results The B M A has for the first time departed from its usual practice of serving only the vested interests of the part-time consultants It is to be hoped that, in the discussions which lie ahead, concern for the problems of the junior grades will be maintained

P WATNEY ROE

LEISHMANIASIS ACQUIRED BY CONTAGION

SIR,—I was very interested to read Professor Symmers' paper of Jan 16, in which he states that it is remarkable that the woman's lesion took the form of an oriental sore typical of infection by *Leishmania tropica*, whereas her husband's disease was of the visceral type associated with infection by *L donovani*

It has been shown [1] that the East African strain of *L donovani* is very dermatotropic in that a primary skin lesion precedes the visceral infection There is a latent period of commonly four to six months during which time only a skin lesion can be found. It is possible in the case described by Professor Symmers that, had the vulval lesion been allowed to continue untreated, visceral spread would have occurred and the woman would have developed kala-azar, or the nodule would have faded spontaneously as can happen in a smaller proportion of cases, without visceral spread The husband was infected, during the early part of the East African campaign, in the Sudan Ethiopian area, where kala-azar infection is common and of the same type as is found in East Africa In East African kala-azar parasites are found in the normal skin in up to 11% of cases, so that infection by direct contact could have occurred in this way

MEDICAL NEEDS OF INDIA

SIR,—I have read with great interest your leade Jan 30, 1960, and I should like to comment on some the points

India is trying through its five-year plans to raise standard of living of its people This,is, at present, extrem low, for the average income is less than £23 per head annum, of which food consumption alone takes 60–70% the first five-year plan (1951–52 to 1955–56) expenditure agriculture, community development, flood control, & formed 32 1% of the total as against 5 9% on health T provision is 20 9% on the former and 5 7% on the latter the second five-year plan (1956–57 to 1960–61) The expen ture on industries, mining, transport, communication, a power, which had the major share, formed 42 3% and 53 3 of the total expenditure in the two plans The total outl of the first and second plans were Rs 23,500 million a Rs 48,000 million respectively The national income increas by 18% in the first five-year plan and it is expected that it w increase by about the same proportion in the second five-ye plan

President Rajendra Prasad, when inaugurating the budg session of Parliament on Feb 8, 1960, said that the object the third five-year plan, the preparation of which was maki good progress, would be to double the national income, taki 1950–51 as the basic level Greater attention would be paid agricultural production and heavy machine building as w as to development of basic resources like steel and power T progress, though not spectacular, is steady and encouraging

On the agricultural front the results have not been encoura ing The area of cultivated land per caput was 1 09 acres 1891, 1 11 acres in 1921, and 0 84 acre in 1951—i e, near one-fourth less in 1951 than in 1921 With the present effo agricultural production in the second five-year plan has be averaging a 3 5% annual increase India will require 11 million tons of food grains a year by 1965–66 when the popul tion is expected to be 480 million, and she will have a shorta of 28 million tons of food grains if the present rate of pr duction continues During the past ten years India has bee importing, on the average, 2 5 million tons of food grains year, at a cost of nearly Rs 1000 million

Probably no single factor is so important for the futu progress of India as the solution of its sudden increas in population For India this has become the bas problem, for on its solution and balanced achievemen depend all future progress Control of famines an epidemics, and the provision of maternity and child welfare services, are lowering mortality and increasin the span of life

The expectation of life at birth in India in 1921–30 wa 26 89 years, in 1941–50 it rose to 32 years, but in 1951–60 it i expected to be about 42 years, a gain of 10 years during th present decade India's population between 1891 and 1920 when the natural checks were operating, increased by 12 millio only, but between 1921 and 1950 it increased by 110 million

It is estimated that India's population, which was 357 millio in 1951, will have expanded to 431 million in 1961, and a present the rate of increase is 2% per annum as against 1 3% per annum in 1941–50 Medical men may be blamed fo bringing about this accelerated rhythm, but no-one can deny that medicine must serve society by conquering killing diseases, preventing epidemics, promoting and restoring health, an prolonging life so that it may be lived and enjoyed to the full But large families and disease may be responsible both for high morbidity and mortality, and population pressures and good health do not go together in countries with a low economy Too often Indian women alternate between gestation and lactation until their premature death The application of scientific medicine to improve the health of the people in underdeveloped countries aggravates the population problem, and as science can be used to reduce deaths it should also be used to reduce births

Government of India realises this fact fully, and the ian Planning Commission clearly states in the second five-ear plan that "The problem of regulating India's population om the dual standpoint of size and quality is of the utmost mportance to national welfare and national planning" The Government, therefore, is actively supporting a family planing programme and is giving it high priority A provision of early Rs 50 million has been made for this in the second lan, and 300 urban and 2000 rural clinics are being set up by the end of 1959 there were 1147 clinics of which 712 were in the rural areas)

The Census Commissioner to the Government of India, in his report on the 1951 census, laid down a national policy by which India could attain a stationary population This should be done by avoiding "improvident maternity"—defined as childbirth in a mother who has already given birth to three or more children, of whom one at least is alive In order to achieve this, the people, 83% of whom live in more than 500,000 villages in India, with no privacy or toilet facilities of any kind, and who are mostly illiterate and ignorant, should have suitable and cheap means of contraception at their disposal. That is the biggest hurdle yet to be crossed in the way of family planning, and it needs serious thought and investigation by the demographers, medical men, and scientists In my opinion, coitus interruptus appears for the present to offer itself as the most practicable method for mass adoption. Oral contraceptives which would be acceptable may take a few decades of experimentation before they can be recommended for mass adoption.

All this, Sir, may seem far removed from the subject of your leading article, but it is only fair to pay due consideration to the background against which the medical needs of India must be assessed We, in this country, are trying to achieve results which "Western" countries have only enjoyed after perhaps a hundred and fifty years of intensive efforts We cannot hope, nor do we want, to imitate all aspects of Western medicine, for our way of life is, and must remain, different We do, indeed, welcome people who are prepared to come and work with us provided that they will stay sufficiently long to learn and understand the customs and habits of the country

May I make one further comment, on your criticisms of the administrative framework While it is true that this medical college is unique in India in that it is directly under the University, which is an autonomous body, all senior academic posts in medical colleges are, so far as I am aware, filled, like my own, after open advertisement and interview by a University Selection Board or the State Public Service Commission on which there are independent assessors or experts

AMINE IN SEARCH OF A FUNCTION

SIR,—Your annotation of Dec 12 with this title seems to imply that this agent is also in search of a name It is variously known as 5-hydroxytryptamine, 5-OH-T, 5-HT (the jazzy variant, 5-HOT has been wisely overlooked), serotonin and, in an early guise, enteramine

The chemical names are specific to a degree but, since they begin with the strident word "five", cacaphonous Trivial names may properly describe functions, among these, our term "serotonin" alludes both to one of the source materials and to this amine's major effect on smooth muscle, while Erspamer's "enteramine" characterises a single, possibly physiological function However, few are so humble as to wish to rest even their primitive central nervous activities on so gutty a base as enteramine (The pun is intentional.) Hence, the term "serotonin" seems both defensible and useful Lastly, it is a pity to burden medical letters, bemuse indexers, and confuse students with increasing numbers of names for the same thing, or further to separate the English and American languages, now divided on such terms as "elevator" and "lift", "braces" and "suspenders", by adding this particular

There may be another solution C of E, Paleyian theology directs us to the view that anything as widely distributed in Nature and active in so many ways must have major significance in the Order of the Universe Since we cannot yet define this in any unitary way, perhaps an alternative to "serotonin"—viz, "confusotonin", once proposed in jest—deserves more serious consideration by some appropriate reference committee

A C CORCORAN

TREATMENT OF ADVANCED CARCINOMA OF THE BREAST

SIR,—In their valuable contribution of Jan 16 Dr Brinkley and Dr Pillers make the dogmatic statement that "operation is necessary because X-ray castration does not completely stop ovarian function" I am sure that many would be grateful to know the evidence for this statement

In the breast clinic in this hospital the œstrogen content of vaginal smears has been seen to fall dramatically following radiation castration, and in other cases no appreciable alteration in œstrogen content has occurred following surgical castration. In these latter cases other sources of œstrogenic function are evidently still active and one would not conclude that the ovarian function had not been completely stopped by the operation. There is also abundant clinical evidence of regression of breast carcinoma following radiotherapeutic castration.

In many instances operation is undoubtedly to be preferred When a rapid response is required in a patient with fulminating and rapidly progressing disease, the effect of surgical castration is more dramatic and more rapid than if ovarian function is affected by external radiation. On the other hand, it is our experience that the menopausal symptoms are less severe if X-ray castration is employed It would, therefore, be unfortunate if the impression were gained that oophorectomy is always to be preferred to radiation castration.

R J DICKSON

IMMUNE TOLERANCE IN MOTHER AND FŒTUS

SIR,—It is difficult to understand why the fœtus, which achieves antigenic competence in utero, is not rejected by the mother by immune phenomena much in the manner that a primary skin homograft would be Many explanations have been proposed for this surprising manifestation of immune tolerance but none has yet received general acceptance Dr Gordon's[1] intriguing hypothesis (Jan 9), with which I cannot agree, prompts me to put forward my own theory which at the present time is based on ample contributory evidence and is strongly supported by preliminary experimental observations

Although Woodruff[2] has postulated that the placenta may protect the fœtus by acting as a millipore filter, no account has been taken of the antigenic action of the placenta itself, which is, after all, of fœtal genetic origin The syncytiotrophoblast may well play an important role in this respect, for this unique tissue is not only the first part of the embryo to come into contact with maternal tissue at implantation but also remains the sole fœtal tissue that ever associates with maternal cells The syncytiotrophoblast possesses many interesting features apart from its syncytial character The nuclei are in general smaller than those of the adjacent cytotrophoblast and, although rapidly multiplying especially during the early stages of development of the placenta, are never seen in mitosis *Syncytiotrophoblast invades the endometrium* with apparent impunity, eliciting no tissue reaction whatsoever Recently, careful search by Sohval and his colleagues[3] has failed to demonstrate the presence of the Barr nuclear chromatin body in the nuclei of these cells in the placentas of female fœtuses, although it has been identified in every other cell type of such placentas

---

[1] Gordon, I *Nature, Lond* 1960, 185, 118, *Lancet*, 1949, i, 807

[2] Woodruff, M F A *Proc roy Soc* B 1958, 148, 68

These considerations lead me to suggest that the nuclei of the syncytiotrophoblast are haploid, possibly possessing only the maternal chromosome complement and thus resulting in a tissue genetically acceptable to both mother and fœtus

Owing to the absence of mitoses it is impossible to test this hypothesis directly by chromosome counts, but the recently developed technique of Feulgen microspectrophotometry for the determination of the D N A content of individual nuclei provides a useful method for attacking this problem Comparative studies of D N A content by this method, chemical estimations, and direct chromosome counts provide excellent agreement and it is established that this is a reliable method to determine the ploidy of any given nucleus[4]

Preliminary results from study of material at present available indicate that the syncytiotrophoblast of immature placentas contains a large number of haploid nuclei Tissue from therapeutic abortions, mature placentas, hydatidiform moles, and choriocarcinomas is now being collected for examination of nuclear D N A content by microspectrophotometry

A full discussion of the implications of this finding and the possible mechanisms involved is presented elsewhere[5]

PAINLESS SKIN BIOPSY

SIR,—Chromosomal studies in man are usually conducted on cultures derived from marrow, blood, or skin Skin has the advantage that it travels well, leads to good preparations without squashing, and is known to be capable of being maintained in culture for many months, but it is often regarded as difficult to acquire

I have found, after taking many skin biopsies from myself, a very simple and painless method which requires little equipment, no local anæsthesia, no aftercare, leaves no scar, and yet provides adequate tissue for establishing culture The term painless may seem exaggerated, but, with practice, this can be achieved Even if inexpertly but carefully performed it is likely to be less painful than venepucture, while failure is impossible

A piece of skin is made lax by gently squeezing between the finger and thumb, and a ridge of this skin is trapped between the shafts of a pair of forceps The shafts should be rounded in cross-section Toothed iris forceps are suitable if care is taken to keep the teeth clear of the skin

The hump which bulges through the gap should be about 1 mm high, 1 mm wide, and 5 mm long, and should not extend as far as the points of the forceps After thirty seconds of gentle pressure the skin becomes pale and opalescent and is found to be completely insensitive The protruding skin is removed by sliding a dry scapel or razor blade along the forceps away from the points For cell culture, skin cleaning should be by some completely volatile fluid, as ether Razor blades are convenient as they may be sterilised in an oven while still wrapped The few drops of blood are adequate for 2–10 slides The resulting wound is flame-shaped, and heals over without contraction, being very shallow, infection is unlikely

The area chosen seems immaterial The iliac crest region is convenient in children and babies, and skin may be taken during sleep

Sections of the biopsy show approximately equal numbers of mesodermal and epithelial cells The specimen is adequate for sexing, although only rarely will this be preferable to the buccal mucosa or the white blood-cells Although small, the biopsy may also be of use in those skin disorders in which relatively rough treatment will not confuse the histology

CLOSED WOUND DRAINAGE

SIR,—Primary closure of surgical wounds is the ideal, and although it is sometimes impossible, there is no longer a place for open drainage of wounds or drainage into dressings Primary closure may be prevented by

The need to drain a duct or a secreting hollow viscus

Where a secreting gland has been transected

The desirability of obliterating a tissue space by the removal of air, blood, or accumulated tissue fluid

The drainage of a productive abscess

The drainage of a site of infection where localisation has not occurred or where a fistula may form

Closed drainage with or without suction has many advantages infection is reduced, wound healing is expedited, the discomfort of soaked dressings is avoided, early changing of dressings is unnecessary, and the cost of treatment is less[1]

The methods used in the surgical department of this general hospital in recent years are

Water-seal drainage with or without suction

Closed drainage for bladder cases

A Penrose drain or pack

Tube drainage with a plastic suction bottle

Thoracotomy demands water-seal drainage, sometimes with suction, and closed drainage in such a case is a well-established method In our practice when any form of suction is applied to the chest, a " three-tube " bottle providing a safety valve is always fitted to the system between the source of suction and the standard water-seal bottle

Closed drainage for bladder cases is also standard Before the operation we use the Gibbon's plastic catheter and bottle[2] After operation whatever catheter is employed, whether urethral or suprapublic, is connected to a Tudor Edwards empyema bottle The neck of this bottle is sealed with a rubber cork, and the air vent is occupied by a thistle-shaped steel cup containing formalin tablets, loosely wrapped in gauze[3]

In some cases tube drainage may be unsatisfactory—for example, in a case of appendicitis with perforation, especially if the appendix is retrocæcal or requiring much dissection It may be unsatisfactory because, though it establishes drainage from one loculus, other pockets of infection may develop in the pelvis or elsewhere *Provided the appendix has been removed* and the appendix base securely closed—that is, if the source of pus formation has been removed and the risk of fistula formation has been minimised—it is better, we feel, to use the Penrose drain This prevents further bleeding and accumulation of fluid by exerting pressure on the raw area, and at the same time it promotes healing and forms a track if infection or fistula formation should ensue This drain is left undisturbed for fiv to six days

If there has been much bleeding, or fluid is likely to accumulate, a drainage tube and suction will not only remove the fluid but also air, and thus reduce the size of any potential cavity (e g , after mastectomy, retropubic dissection, neck dissection renal surgery, and the removal of large space-occupying tumours) If a secreting gland has been transected, as in partial thyroidectomy, there is a further indication for drainage.

[3] Riches, E W *Practitioner*, 1952, 169, 388

Evacuation of an abscess leaves behind a pyogenic cavity which continues to produce infected material Closed drainage prevents the dissemination of infection, at the same time keeping the cavity empty and reducing its size

In this group of cases we use closed drainage with suction, employing polyethylene bottles No originality is claimed for the method but it has proved so successful that we feel its advantages should be more widely known For the drainage tube we use a plain rubber or portex catheter of approximately size 10 (English gauge) To this is attached a light polyethylene bottle which has a screw-on cap with a tapering nozzle, also made of polyethylene. The walls of the bottle are lightly compressed as the nozzle is inserted into the end of the catheter, so that a low negative pressure is created, sufficient to draw pus, blood, or serum from the far end of the catheter into the bottle.

The advantages of this method are numerous

Dressings remain clean and need not be changed in the early postoperative days when the wound is most tender Economy in dressing materials and nursing time is considerable and bacterial dissemination is reduced

It is a simple matter to check at any time that the system is functioning efficiently

One has a sterile and immediately visual method of assessing when the drain might have fully served its purpose and be withdrawn without any need to disturb the dressing

The quantity of drainage is measurable, and can be recorded on the patient's fluid chart when appreciable in amount

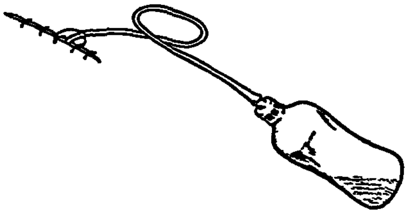
The bottles are made of low density polyethylene and are very light to handle.

They are cheap and can be used many times

This suction drain operates continuously and silently with very little supervision

The patient can be fully ambulant while suction is maintained

Attention to the following practical points is important The drain tubing must be firm enough so that it will not collapse with the negative pressure For this reason we use a Jacques or Harris catheter with several extra holes cut The fluted proximal end allows easier insertion of the nozzle and can be cut to the size required for a secure fit The catheter is held by a double suture inserted close on each side (see figure) and it is important to avoid puncturing the catheter with the needle



It is essential to avoid over-compression of the bottle especially after repeated use, otherwise it will become kinked and will not re-expand The bottle interior is sterilised by filling with a 1 in 20 solution of carbolic and there has been no sepsis attributable to the use of this method. Two sizes of bottle (4 oz and 10 oz.) have been used, the smaller size being suitable for most cases Experiment has shown that both sizes of bottle can draw up a column of water 4 mm in diameter to a height of 100 cm. After repeated use the polyethylene tends to harden and the suction power is reduced This negative pressure has not given rise to any complications in practice and compares favourably with the use of many electric pumps which may go on building up an ever-increasing negative pressure Moreover, they effectively immobilise the patient and may cause considerable annoyance if the pump is noisy The polyethylene bottles, on the other hand, are eminently portable and silent

Despite the limited calibre of the catheter and dispenser spout, there has been no tendency to blockage We are at present experimenting with nozzle fittings of different shape and size The screw-on top is being retained, however, because of the access it allows for cleaning

I am grateful to Mr J Hutchison for much helpful criticism and advice, and to Mr P S Waldie, A.R P S for the diagram

Glasgow

F T CROSSLING

BONE-MARROW GRAFTS IN LEUKÆMIA

SIR,—In the discussion of the use of autologous marrow grafts in your leading article of Jan 23 mention is made of three of our cases of leukæmia in which we employed total-body irradiation and infusion with autologous marrow obtained during a remission[1] It might be of interest to add the follow-up of the patient in whom a remission was achieved by this procedure

The patient, a 2-year-old girl, remained well until the 84th day after irradiation, when the liver, spleen, and lymph-nodes were observed to be enlarged, and a bone-marrow aspirate showed recurrence of leukæmia. A-methopterin therapy, to which she had become refractory before irradiation, was reinstituted, with some regression in the size of the lymph-nodes and a fall in the white-cell count However, she died while being given a blood-transfusion 102 days after irradiation. Postmortem examination showed leukæmic involvement of the liver, spleen, lymph-nodes, bone-marrow, and kidneys Several walled-off splenic abscesses caused by *Staphylococcus aureus* were present In addition to involvement by leukæmic infiltrates the lymph-nodes showed scattered follicles, and the stomach and intestines contained many prominent lymphoid follicles with germinal centres

Although a remission was obtained in this one case, we believe that further investigation is necessary to determine whether bone-marrow grafts are of practical value in the treatment of leukæmia

DISCHARGE FROM A HOSPITAL VACUUM SUCTION SYSTEM

SIR,—A piped vacuum system is being installed in New Guy's House, which is now under construction This department was asked to advise whether there was any danger from the exhaust from such a system, which might collect pathogenic organisms, particularly antibiotic-resistant staphylococci, and discharge them into the atmosphere As inquiry revealed no information on this matter, it was decided to investigate an existing vacuum system That at the Royal Marsden Hospital was selected

It was installed in 1948 and consists of suction points, in three operating-theatres, a reservoir tank, and a pump in the basement with a discharge pipe to a basement yard. The vacuum is maintained between 15 and 25 in. of mercury Through the cooperation of the Royal Marsden Hospital and British Oxygen Gases Ltd, the following investigations were carried out

(1) Three sections of pipe were cut out—near a suction point, in the main vacuum line from the theatre floor, and just before the tank The inside of each pipe was found to be dry and macroscopically clean Swabs were taken from these three sites and from the inside of the tank. Direct plating produced no growth, and enrichment in broth grew *Staphylococcus albus* and diphtheroids from two swabs only

(2) The effluent air was sampled by passing it through a plug of sterile alginate wool of approximately 1 cm diameter which was then dissolved in a 1% sodium hexametaphosphate solution containing 10% horse serum The resulting solution was cultured Two tests were made on different days in which 150 and 200 litres of air (as measured by a gas meter) respectively were pumped On the first occasion the vacuum was broken at the entrance to the tank, no organisms were recovered On the second occasion the vacuum was broken at a suction point in a theatre so that air was drawn through most of the system *Staph albus* was isolated, on enrichment only

Quantitative control tests using *Staph aureus* showed that the solvent used was not significantly inhibitory

---

[1] *New Engl J Med* 1959, 260, 675

(3) The tank was opened by British Oxygen Gases Ltd , and was found to be surprisingly clean No fluid was present, but there was evidence that there had been a pool of liquid at some time, as there was a "high water mark" of encrusted deposit When this was examined under the microscope no microorganisms could be seen and it yielded only a micrococcus and an aerobic sporebearing organism, separately from two enrichment cultures

Thus it was not possible to isolate any pathogenic organisms from the system examined, and non-pathogens could be recovered only by enrichment methods The difficulties of using an aseptic technique in the circumstances described do not rule out the possibility of chance contamination The low level of contamination was a little surprising, but it may be due to the dry conditions inside the vaccum system, the lack of nutrients, and possibly the fact that much of the piping was of copper "Heat-sterilisation" of air has been achieved by adiabatic compression in reciprocating compressors,[1] and the pump in the system here described may have been acting in this way

The significance of one set of tests on a single vacuum system is doubtful, and different results might be obtained in a hospital where many septic cases were treated, but it is thought that the information obtained is of sufficient interest to be worth reporting

DEPRESSION AND IMIPRAMINE

Sir,—Undue sweating has been described as a side-effect of imipramine ('Tofranil') It appears to me, after a certain amount of experience with this drug and its effects on endogenous depression, that those patients who respond well tend to complain of undue sweating in the early stage of their treatment, whereas those who do not respond do not notice any such sweating

Can it be that we have here a sign of prognostic import which might be useful in determining whether it is worth persevering with this drug in certain cases?

I should be extremely interested to hear from your readers who have perhaps greater experience with imipramine whether they have noticed any such correlation between excessive sweating and good prognosis

London, W 1

R Cedric Simpson

CHROMOSOME COMPLEMENT IN A MONGOLOID MOTHER, HER CHILD, AND THE CHILD'S FATHER

Sir,—Of the three human diseases due to a chromosome abnormality—mongolism, Klinefelter's syndrome, and Turner's syndrome—mongolism is the only one in which instances of fertility have so far been reported To our knowledge there are six reports of women with mongolism having had a child which was adequately described [2–7] Three of the children were mongols [3 6 7] It is of obvious interest to obtain information on the karyotype of these fertile mongoloid patients and their offspring Levan and Hsu [8] have briefly mentioned the result of such a study in a mongoloid mother whose son had a normal chromosome complement

We have investigated a mongoloid mother, her son, and the reputed father by determining the chromosome complement of cells cultivated in vitro A detailed description of these individuals was given by Forssman and Thysell [4] Bone-marrow cells were cultivated according to a technique described by Fraccaro et al [9] The 35-year-old mother had 47 chromosomes The apparently normal 5-year-old boy and the father, a 59-year-old blind man with epilepsy, had normal karyotypes of 46 chromosomes

Further details will be published elsewhere

AUTOGENOUS VACCINES AND THE COMMON COLD

Sir,—I must apologise for writing you a long letter on this subject, but the trial reported in your issue of Feb 13 requires some strong comments This R A F trial, although using the same vaccine, was conducted on essentially different lines from that reported by me in 1958 The points of difference are

(1) Last paragraph of preamble (p 358) "The vaccines were prepared in the same way as Ritchie had prepared his, but the dosage schedule was modified, as weekly injections would not be welcomed by healthy men and would be difficult to arrange on an operational flying station" The variation in the dosage schedule invalidated the whole R A F trial from the beginning Our trial, which, it must be noted, really lasted for over 25 years, depended on the maintenance of immunity over a period, by regular weekly injections, not by a mere token series of three in October plus one single injection in January As I pointed out at the time, that system of dosage is completely subminimal and useless, rendering their results quite valueless They can in no way be compared with the results I reported in 1958

(2) The next sentence in the same paragraph on p 358 reads "Furthermore there seemed to be no theoretical reason why weekly injections should produce a better immunological response than a more usual course" There is no "usual course" in a prophylactic cold vaccine of this kind No-one has tried the procedure but myself, and I have found from experience that the only course is one of weekly injections throughout the part of the year concerned If the R A F found this impracticable they should not have tried a makeshift substitute of their own, much less have attempted to compare it as if it were on the same lines as previous work. The phrase "usual course" suggests a complete confusion of mind between coccal vaccines and those prepared for the zymotic diseases, such as typhoid, where one attack confers lifelong immunity, more or less Anyone who has used *Staphylococcus aureus* vaccines, for example, over a period of years with 100% success, as I have, knows that these coccal vaccines must be maintained over a considerable period to get the result That is the "usual course" for a coccal vaccine, not a few haphazard doses at intervals

Table III (p 360) has an interesting comment, that volunteers who were vaccinated did not lose less flying-time "except to a small degree during the first 2 weeks after inoculation with autogenous vaccine" In other words, during that period the vaccine was beginning to work, but with the cessation of regular injections the effect was lost Had these been carried on the results might well have been greatly different The comment on table IV shows a similar trend

"There was, however, an interesting reduction in the incidence of illness in the autogenous-vaccine group in the period when it might be expected, between the 3rd and 6th weeks after inoculation" This fits in with my comment in the previous paragraph and again suggests that the vaccine was beginning to work

It is also observed that "a vaccine designed to prevent secondary bacterial infection would be expected to reduce the severity of illnesses rather than their incidence" That is frankly nonsense Vaccines of this kind are intended to promote resistance and therefore to reduce incidence Once resistance is overcome, the severity of an illness depends chiefly on the virulence of the infecting agent, and an infection powerful enough to overcome an enhanced resistance will necessarily be severe Even typhoid, if I may quote a zymotic vaccine as a parallel in this case, is not necessarily milder in the vaccinated when it occurs

---

[1] Sykes, G , Carter, D V *J appl Bact* 1954, 17, 286
[2] Sawyer, J M *Amer J ment def* 1949, 54, 204
[3] Lelong, M , et al *Arch franç Pédiat* 1949, 6, 231
[4] Forssman H , Thysell, T *Amer J ment Defic* 1957, 62, 500
[5] Schlaug, R *Acta genet* 1957, 7, 533
[6] Rehn, A T Thomas, E *Amer J ment Defic* 1957, 62, 496
[7] Stiles, K A Proceedings of X International Congress of Genetics, Montreal 1958 vol 2, p 276

[9] Fraccaro, M , Kaijser, K , Lindsten, J *Ann hum Genet* (in the press)

In short, this R.A F test proves nothing except that a thing is not worth doing unless it is well done The only sentence with which one can wholeheartedly agree is the last in the paragraph under Comments, that "autogenous bacterial vaccines, perhaps in greater dosage, may therefore merit further investigation among less healthy persons" Even here the word "perhaps" should be replaced by "certainly"

Birkenhead J MORRISON RITCHIE

PERTHES' DISEASE

SIR,—You annotation of Feb 16 refers to my finding[1] that in cases of Perthes' disease with partial involvement of the upper femoral epiphysis the prognosis was better than in those cases in which the whole epiphysis was involved A study of my figures will show that this is so, when variations in age and sex have been eliminated The prognosis appears to become much worse if the child is eight years old or over at the time of diagnosis

In regard to the long-term end results neither the figures of Ratliff[2] or of Professor Trueta[3] absolve the orthopædic surgeon from adopting full treatment immediately

Often in the young child the disease damages the whole epiphysis or a large anterior segment of the head Traction in recumbency until reconstruction begins, followed by the wearing of a patten-ended calliper, gives good results in these hips Mild cases do not require recumbency In older children treatment does not seem to affect the result.

NORADRENALINE EXCRETION IN INDIAN SUBJECTS

SIR,—Floyer[4] described a simple biological test for an approximate estimation of urinary noradrenaline Urine was injected intravenously into an anæsthetised rat and the rise in blood-pressure was measured This simple technique has been used to estimate the noradrenaline content in the 24-hour urine samples in eighteen Indian subjects (fourteen hypertensives and four controls)

A slight modification in the anæsthesia was that 0 6 ml per 100 g body-weight of 25% urethane was injected intraperitoneally, and no further subcutaneous injections of urethane were given to prolong the anæsthesia for several hours

The results indicated that the excretion of noradrenaline in Indian subjects is about the same as that described elsewhere[5] In thirteen of the subjects the noradrenaline content was 65 μg or less in 24 hours Robson and Keele[6] stated that the normal concentration of catecholamines in urine is 5–15 μg per 100 ml. urine. In our results seven subjects had a noradrenaline excretion equivalent to 1 5 μg per 100 ml or less, while four excreted less than 4 μg per 100 ml urine It is possible that values less than 5 μg noradrenaline per 100 ml urine are normal for Indian subjects

The method described by Floyer[4] is a simple and convenient way of estimating the noradrenaline content of the urine and screening cases for phæochromocytoma The noradrenaline content in 24-hour urine in Indian subjects appears to be nearly of the same order as in other subjects described previously

I should like to thank G S Ahluwalia for his excellent technical assistance

PREVENTION AND TREATMENT OF BEDSORES BY SILICONE CREAM

SIR,—I should like to add a note to the report of Dr Roberts (Jan 30)

During the past two years, I have treated 80 patients in this hospital—the majority of whom were incontinent—with the creams I and II made and kindly supplied by Messrs Ward Blenkinsop Cream I containing dienœstrol is the more effective and is excellent for the prevention of sores when the skin becomes reddened at pressure points, for superficial bedsores, and for accelerating healing when deeper sores are beginning to fill in

I did not, however, find it adequate as the sole dressing in treating deep bedsores, for which I still follow my previously published routine of changing the application used every three days until healing is initiated.

Putney, London, S W 15 V KENDALL

RECESSION OF EXOPHTHALMOS AFTER MASSIVE DOSES OF RESERPINE

SIR,—Sir Russell Brain[1] emphasised that, in sera from exophthalmic cases, a hypophyseal substance similar to T S H is present Dobyns and Wilson[2] produced exophthalmos in the minnow by injecting the serum of patients with severe or progressive exophthalmos, and their findings suggested some correlation between the degree of response in the fish and the stage and severity of the patients' exophthalmos Barraquer and Canadell[3] made similar observations We should like to describe a patient with exophthalmos who reacted favourably to reserpine

A woman of 45 was admitted to hospital in 1959 because of paranoic psychosis accompanied by disorientation, amnesia, depression, and suicidal drive She had undergone thyroidectomy in 1944 because of Graves' disease, and a partial adrenalectomy in 1951 for phæochromocytoma Apart from the psychotic disturbances, severe diencephalic and endocrine insufficiency syndromes had developed in the patient The most troublesome symptom was severe exophthalmos For six months she had no menstrual cycle, apparently because of incipient menopause.

Reserpine (10 mg daily) was injected intramuscularly Definite improvement in the exophthalmos was noticed after five days, whereupon the reserpine was discontinued Within a week, the exophthalmos recurred as badly as before Reserpine was renewed, and by the eighteenth day the exophthalmos was hardly noticeable

Urinary F S H was continuously assayed during this period, decreasing from 50 rat units per litre before treatment to less than 25 later This improvement in the exophthalmos and the endocrine symptoms did not, however, produce any obvious change in the psychosis, and disorientation, amnesia, and depression persisted

We have been able to show that reserpine depresses some pituitary tropins, especially F S H, apparently via the hypothalamus, and we therefore assume that in the patient whose urinary F S H levels were high, reserpine depressed the pituitary secretion of both the exophthalmo-

TREATMENT OF CEREBRAL FAT-EMBOLISM

SIR,—Reading the article[5] by Dr Harnett and his colleagues, I was surprised at the remark, " Attempts at specific treatment have not been very successful " I do not agree and I wish to draw attention to two articles published during recent years

(1) The first[6] was concerned with the excellent results of decholin therapy, as described by Rappert,[7] obtained in the O L Vrouwe Gasthuis, Amsterdam

(2) The second paper[8] was also concerned with the decholin therapy of fat-embolism Results showed that only 8 out of 100 patients with severe fat-embolism died A very successful treatment indeed

Amsterdam A G J VAN SONDEREN

Public Health

Influenza

ACUTE respiratory infections have been increasing in past weeks in the Northern Hemisphere As in every year since 1957–58, the World Health Organisation reports, the outbreaks seem to be mainly due to the A2 (A/Asian) virus, although in some places, notably Finland, virus B seems to be responsible The disease is nowhere as widespread as in 1957–58, and is generally benign and of short duration, although as in every influenza epidemic there are some deaths from pneumonia, usually in elderly people or those suffering from other diseases The situation as reported to W H O is as follows

United States—In the week ending Jan 23 there were localised outbreaks of influenza, but absence from schools and in industries most affected by the disease did not exceed 15–20% Influenza due to virus A2 was confirmed in 12 States and the District of Columbia, and there were reports of epidemics of acute respiratory infections of which only a few were confirmed to be influenza in 11 others

France—The epidemic is more important in the country than in Paris, the principal centres of infection being the east, centre, south-west, and south-east Virus strains have not yet been identified

Netherlands—Virus A2 was isolated from a fatal case of virus pneumonia in The Hague

Sweden—Localised outbreaks of a mild influenza-like disease, which has not yet been identified, have been reported from several garrisons in the north and south of the country, but so far there has been no spread to the civil population

Switzerland—The number of influenza cases reported grew from 385 in the week ending Jan 16 to 2837 in the week ending Jan 23 The cantons of Zurich, Basle-Town, Geneva, and Grisons were the worst affected

In this country the Ministry of Health's weekly influenza statement for the week ended Feb 13 said there had been no laboratory evidence of influenza virus A or B, nor other evidence of the prevalence of influenza

Medicine and the Law

A Partner's Notes

AT the hearing of a wife's petition for divorce on the ground of cruelty, a doctor who had seen the wife from time to time over the past few years was called to give evidence relating to her health This doctor, who was in partnership with another doctor, used, for the purpose of refreshing his memory while giving evidence, the wife's medical history card This card recorded dates upon which the wife was seen, complaints made by her of her husband's behaviour to her, of her own health, and the treatment prescribed The card contained notes made not only by the doctor giving evidence, but also by his partner relating to an occasion when the partner saw the wife The question arose whether the witness could give in evidence notes recorded by his partner, the latter not being called as a witness

Mr Justice PHILLIMORE ruled that by the Evidence Act 1938 notes made by the partner could be given in evidence, in so far as the notes recorded facts, such as the date on which the wife was seen and the treatment prescribed, but that the notes concerning the complaints made by her were not admissible

Social Workers and Their Training

ON Feb 17 the EARL OF FEVERSHAM drew attention to the Younghusband report[1] and sought the Government's reactions to its recommendations His own were favourable, for he believed that lack of training and status had lost the social services many potential recruits in the last fourteen years The local authorities' growing responsibilities under the welfare and health Acts made the recruitment of more social workers a matter of urgency He was particularly impressed by the need for trained mental-welfare officers, 40% of the present officers were due to retire within the next ten years

Lord AMULREE felt that the training proposed in the report was a trifle on the theoretical side He was also uneasy about the report's tendency to regard the health and welfare departments as separate entities In his view there was some sort of medical aspect to most welfare and social work and he would like to see the welfare and health departments, if not combined, which would be ideal, at least working closely together, with the medical officer of health a member of the two committees or having both working under his care

Baroness WOOTTON OF ABINGER thought that some of the report's recommendations were not entirely realistic The grading of the workers and the classification of the cases seemed to her too tidy In practice people might be handed from one worker to another One of the besetting diseases of our community was a delight in professionalism for its own sake Another was a tendency to confuse the economic and psychological She would be the last to dispute that where there was a problem of mental health, psychological training was essential, and it was deplorable that so few of our mental-welfare workers had had that kind of training But she thought that interest in psychological problems sometimes led to failure to discriminate between a plain practical need—often lack of money—and a true mental or psychological difficulty In her view many of the problems with which the social worker had to deal were basically economic People who had fallen into difficulties from lack of money should not be treated as though they were failures in personal or social functions, and she hoped that the Government would be cautious in the type of training which they provided for the modern social worker. Might the report be made the occasion for fresh thinking about a new orientation for the role of the social worker in our society?

[3] Schmitter, H *Münch med Wschr* 1958, 43, 1658

[1] *Lancet*, 1959, i, 974

Baroness SWANBOROUGH was worried about the suggestion in the report that people who were at present doing good work should have to submit to further training. She welcomed the idea of a form of training but thought that the over-elaboration which came with an obsession for professionalism was a hazard. She agreed that there was infinite danger in assuming that because people were in financial need they must be handled by trained social workers. Social welfare was a continuing process, and trained workers should have volunteers to continue the work at the local level. Voluntary service should be the mortar between the bricks of officialdom.

Lord TAYLOR agreed that it would be better not to categorise too much in planning the future training of social workers, and he thought that perhaps the idea of the welfare assistant could go. But everyone was agreed on the need for many more social workers. The question remained: would the Government pay the extra salaries which these people would have to get?

The main message of the report, Lord ST OSWALD had found, was that social-work services needed more training and more manpower. To him the two went hand in hand, for one of the incentives to recruitment would be training. To this end the Younghusband Committee had made purposeful and detailed proposals. The Government were grateful to the authors of the report and were now weighing, not only their advice, but the advice they had drawn from other quarters. The recommendations must be considered in the light of local-authority views. Equally, several departments, including the Ministry of Health, that of the Secretary of State for Scotland, the Home Office, the Ministry of Education and, last but not least, the Treasury were closely concerned. The local-authority associations and the main voluntary bodies had already expressed their general views. It might be necessary now to obtain their views on specific details, but time would not be wasted.

Welfare of Office Workers

THE Offices Bill was introduced as a private member's measure by Mr Richard Marsh on Dec. 11. Although the Government felt that it should not proceed, the second reading was carried.[1] The Government have now signified their support by tabling a money resolution authorising an increase in the payments to local authorities to meet the cost of enforcing the measure.

QUESTION TIME

Locum Tenens

Mr L. A. PAVITT asked the Minister of Health if he was aware of the inadequacy of the present arrangements to employ locum tenentes in general practice and the hospital services.—Mr WALKER-SMITH replied: I am aware that individual difficulties sometimes occur, but I am not clear that action by me would be appropriate. Mr PAVITT: In view of the fact that so many of these difficulties occur because of the time taken to solve these problems of locum tenentes, will the Minister give consideration to the introduction of a scheme for a local service, and further, will he consider the possibility of using the trainee assistants scheme in order to help in this respect? For example, if the trainee were given two months at the end of his normal training period to enable him to obtain wider experience on a general basis and also in hospitals that would help. Will he also consider the possibility of refresher courses for consultants and specialists, so that they may come down into the arena of family doctoring, which might be beneficial to them and help the general practitioner in solving his problem of locums?—Mr WALKER-SMITH: On the first of those three points, I doubt whether an organised service of the sort suggested would really meet the case because there are so many and varied personal factors involved in these matters. On the second point, I should like to consider the suggestion. The third point is very revolutionary in a professional service, and I think that, like Agag of old, I had better tread delicately.

Dr EDITH SUMMERSKILL: While not asking the Minister to commit himself now, will he reconsider his first answer? As he realises, the great majority of doctors today are employed by the State and find it very difficult to obtain a deputy in case of illness; in fact, there is no certainty that they can obtain a deputy. This also applies during holidays. We should at least equate doctors with Civil Servants so that deputies who can be relied upon are available. Perhaps the Minister will reconsider the whole matter?—Mr WALKER-SMITH: I am always ready to consider further these matters, but I was giving my impression as it now stands. We should not exaggerate the difficulties about locums. In particular, we have to remember that there has been a considerable increase in the number both of general practitioners and hospital doctors overall. These difficulties have to be seen against that more satisfactory background.

---

Obituary

FRANK BARNES

M.S. Lond., LL.D. Birm., F.R.C.S.

Mr Frank Barnes, consulting surgeon to the Birmingham General Hospital, had made many gifts to the United Birmingham Hospitals and the Medical School, and a ward in the Queen Elizabeth Hospital is dedicated to him. The postgraduate surgical travelling fellowship he endowed in 1944 has enabled young surgeons to widen their experience by working abroad. More recently he gave generously towards the building of the new library at the Medical School which, in recognition of his own and the late Stanley Barnes' distinction and generosity, has been named the Barnes Library. Mr Barnes was to have performed the opening ceremony last October but to everyone's sorrow he was too ill to do so. He died on Feb. 18 at the age of 90.

He was born, lived, and worked in Birmingham all his life. After qualifying from Mason College, Birmingham, in 1898, he took the degree of M.B. Lond. two years later. He held many resident surgical appointments before being elected to the honorary staff of the Birmingham General Hospital in 1903. He was also consulting surgeon to the Birmingham and Midland Eye Hospital, the Hospital of St. Cross, Rugby, and the Sutton Coldfield Cottage Hospital, and for ten years he was on the staff of the Birmingham Orthopædic and Spinal Hospital (now the Royal Orthopædic Hospital). During the 1914–18 war he served in the R.A.M.C.

As a teacher he was lucid and orthodox and in the University was lecturer in anatomy and operative surgery. He published little and he evaded high office and public recognition, but he served as president of the Midland Medical Society in 1930. In 1957 the University of Birmingham conferred on him the honorary degree of LL.D.

A. G. W. writes:

"Mr Barnes was a surgeon of outstanding ability, combining high diagnostic acumen with superb operative skill and dexterity and these qualities and his quiet, friendly, and unassuming personality made him one of the most sought after surgeons in the Midlands over many years. He practised in the days before the increasing diversity and complexity of surgical techniques demanded narrow specialisation and he was essentially a general surgeon, but his major interests were abdominal surgery and neurosurgery. He was one of the first surgeons in England to operate successfully on tumours of the spinal cord.

"Although they were not related, Mr Barnes and the late Stanley Barnes were close friends and they spent much of their leisure together fishing, playing golf at Moseley Golf Club, and bridge at the Clef Club. Mr Barnes was also a keen gardener and a connoisseur of wines His death ends a long and happy life of great achievement and distinction, during which his kindness, generosity, and warm nature won him many friends "

OLIVER FRANCIS HAYNES ATKEY

C M G , M B Lond , F R C S

Dr Atkey, a former director of the Sudan Medical Service, died in London on Feb 11

He was a student at King's College Hospital before it moved to Denmark Hill, taking his M B Lond in 1904 and his F R C S the following year After holding house-appointments at King's College Hospital and the Royal Free Hospital he joined the Sudan Medical Service in 1907 Like all new recruits at that time he spent several years doing reliefs and special assignments in the six northern provinces After the 1914–18 war he was appointed to Wad Medani in medical charge of the Blue Nile province, south of Khartoum, which was then being developed as the great cotton-growing area of the country In 1922 he was appointed director of the service, and he held this administrative post till 1933

H C S writes

" During the first nine years of Atkey's directorship, the Sudan Medical Service shared in the general development of the country Its work increased fourfold and more of the southern and eastern provinces came under effective medical control Important training schemes were either inaugurated by Atkey or were greatly developed under his inspiration, and the Kitchener School of Medicine for Sudanese students was opened in 1924 It was almost entirely due to Atkey's efforts that money was raised not only to pay for the buildings but also to provide a sum of £E24,000 as a nucleus for an endowment fund By 1931 the effects of the world slump reached the Sudan, and for a time progress in all Government departments ceased Recovery however was rapid and by the time of Atkey's retirement in 1933 expansion had been resumed

" He was a keen horseman and he played polo and tennis with his customary vigour He did not practise after leaving the Sudan but travelled widely, often by air in his own plane with Mrs Atkey as co-pilot This special interest terminated in a crash in central Africa when en route for the Cape During the late war he was employed in organising and inspecting first-aid posts in the London regional area For the last four years he had been in poor health and his activities were seriously curtailed In his own sphere he had played an important role in the Sudan's growing capacity for independence "

RUPERT GEORGE ANDERSON

M D Edin , D P M

Dr R G Anderson, one of the Lord Chancellor's visitors in lunacy, died on Feb 12

He was educated at Glasgow Academy, Loretto School, and Edinburgh University, where he graduated M B in 1924 He joined the London County Council mental service in 1925, and held posts at Long Grove Hospital, Cane Hill Hospital, and Horton Hospital, where he was deputy medical superintendent In 1938 he was appointed a commissioner of the Board of Control and, apart from three years during the late war in the Middle East as a lieut -colonel in the R A M C , he remained with the Board until 1953, when he was made a Lord Chancellor's visitor

W D N writes

" Anderson was a most delightful colleague, loyal and conscientious He was truly loved by both patients and staff He was a good clinician and in his duties as a Chancery visitor he exhibited great tact and shrewdness His courtesy and manner were almost Victorian In many ways he was a born actor and mimic, full of good humour He will be greatly missed by his colleagues and many friends in the provinces "

Dr Anderson is survived by his wife, a son, and two daughters

GILBERT WINTER DRYLAND

M B Cantab

Dr G W Dryland, who died on Feb 3, qualified at Guy's in 1907 Before the first world war he had settled in practice at Kington in Herefordshire where he spent the rest of his life

R E I writes

" Dr Dryland lived life to the full and delighted in it He was a keen nature-lover and antiquarian Kington, lying in the little known border country between England and Wales, with its rolling hills, its flower lanes, its clouds and sunshine, its meadows fenced with white iron railings, its streams running to the Wye Valley and its half-timbered houses, meant much to him, and he captured its beauty in photographs which adorned his home His garden was as lovely as any I have known He also enjoyed travelling and sailing He was a pioneer motorist who owned a car when motoring was still an adventure It always gave him pleasure to recall how his first car would only climb a certain hill if driven backwards

" Perhaps his most endearing characteristic was a beautifully quiet sense of humour which kept peeping out in all he did It informed a great deal of his writing and made it a joy to receive a letter from him Several Guy's men, of whom I was one, enjoyed doing locums in Kington for him, for to do so was to see country practice at its very best He was sustained by a deep religious faith and was as much beloved for his kindness and gentleness as for his great experience and professional skill "

VASSILI ALEKSEEVICH GILYAROVSKI

Dr Gilyarovski, professor of psychiatry at the Second Moscow University, died last year at the age of 83

Gilyarovski came from a poor family in Southern Russia and began to work for money early when he was still a schoolboy and student, coaching pupils and taking part in anti-epidemic campaigns, in mass-vaccination, and in other social activities among the population He studied under Korsakov, Serbsky, Kozhevnikov, and especially under the physiologist Ssechenov for whom he had a great admiration After serving his apprenticeship in mental hospitals and after some work in neuropathological laboratories, his main interest became the treatment of neurotics and of minor psychiatric abnormalities He did psychiatric work with children and organised speech therapy, was at one time an advocate of the psychoanalytic ideas of Freud in Russia As president of the Society of Psychiatrists and Neuropathologists he took an active part in the extension of the network of psychoneurological clinics in all towns of the Soviet Union, and he drew up rules for these institutions providing full-time care, and day-hospital care, and guardianship He was always much concerned with the practical side of medical work In the early '30s he seems to have conceived the idea of the day hospital as a new type of psychiatric institution

W M -G writes

" From his preference for humanitarian and pathogenetically well-founded therapy methods came his opposition to the extensive use of electro-shock in psychiatry and to leucotomy It may well be that the latter was prohibited in the U S S R on the instigation of Gilyarovski He himself elaborated what he called a physiological method of treatment ' electrosleep ' and wrote a monograph about it This was an electrically induced sleep state, based on Pavlov's idea of the importance of protective inhibition in the cortex Gilyarovski's scientific views were towards his later years very much influenced by Pavlov, who himself provided a comprehensive theory of psychic phenomena on the basis of his physiological concepts of reflex activity Gilyarovski tried to extend and to confirm Pavlov's views, and it may well be that he was one of those responsible for the undisputed prevalence of Pavlovian ideas in modern Russian psychiatry "

Notes and News

PROGRESS IN IMMUNOLOGY

LONG a source of tools indispensable to bacteriology, blood-transfusion, and diagnosis, immunology has latterly become an enlarging area of biological research Everywhere there is talk of its new facts and new theories, particularly those relating to immunological tolerance and autoimmunity Perhaps because of their apparent relevance to problems of surgery and medicine, many workers are now concerned with the mechanisms of antibody responses, especially at the cellular level, and their relation to tissue reactions

An impressive share in the recent advances belongs to the Walter and Eliza Hall Institute, Melbourne, and to its director, Sir Macfarlane Burnet His annual report on the work of the institute[1] is a reminder of what is being done there on the fundamentals of immunology Current investigations deal among much else with the production of antibody by single cells, the cellular transfer of antibody-producing capacity and of characteristic responses, and the genesis and regeneration of plasma cells Work is also in progress on the behaviour of tolerant cells in many situations, on the metabolic activity of lymph-nodes, and on the production of autoimmune disease experimentally by cell transfer Throughout, the emphasis is on the immunological reactions and relationship of cells and their subcellular components—an approach which keeps the institute well to the fore in biological research The clinical research unit there provides a medical link with the experiments Clinical studies in the immunology of, for example, systemic lupus erythematosus, lupoid hepatitis, thyroid disease, and macroglobulinæmia have produced interesting new facts—sometimes puzzling ones

One of the chief problems of autoimmune disease, whether clinical or experimental, is the relative significance in the disease process of the various antigen-antibody systems which are being discovered Little headway has yet been made in characterising specific antigens involved in tissue reactions Progress at the Melbourne institute encourages workers elsewhere in the attempt to define the extent and importance of immunopathology in human disease

MEDICAL REFERENCES

THE first issue has now appeared of the *Index Medicus*, which is to replace the *Current List of Medical Literature* of the National Library of Medicine of the United States Department of Health and the *Quarterly Cumulative Index Medicus* of the American Medical Association. The new index will be published monthly by the Library, and sold by the Superintendent of Documents, U S Government Printing Office, Washington 25, D C (*$20 per year, $25 foreign, single* copies $2 25) The monthly issues will be collated each year, and an annual *Cumulated Index Medicus* will be sold by the Association

Postgraduate Medical School of London

At a reception on Feb 17 at Hammersmith Hospital, the guests were received by Lord Alexander of Tunis, president of the school, and Lord Coleraine, chairman of the school management committee Lord Alexander spoke of the help the school was receiving from the Dominions, particularly in the matter of the appeal to finance the new buildings The appeal had started very well in this country, Pakistan and South Africa had contributed generously, and, Lord Alexander added, Canada was able to play her part, now that income-tax difficulties had been overcome, thanks to the generosity of Canada and Lord Coleraine's personal help Lord Coleraine said that when the extent of Dominion aid was known, it would be decided whether to complete the appeal in this country the essential was that the buildings should go straight on to completion.

University of Leeds

Mr C P Mills has been appointed clinical lecturer in otology, and Mr Verna Wright lecturer in the department of medicine (for rheumatism research)

University of Manchester

Dr Ralston Paterson, lecturer in clinical radiotherapy, has been granted the status of professor, with the title of professor of radiotherapeutics He will continue to hold his appointment as director of radiotherapy at the Christie Hospital and Holt Radium Institute, Manchester

Dr Paterson was educated at George Heriot's School, Edinburgh, and the University of Edinburgh, where he graduated M.B with honours in 1923 After postgraduate study at the University of Cambridge he took the D M R E in 1924 From 1926 to 1930 he held appointments in Minnesota and Chicago, and in 1930 he was appointed acting director of the radiological department in the Edinburgh Royal Infirmary The following year he moved to Manchester to take up his present appointment at the Christie Hospital and Holt Radium Institute He has been a part-time member of the staff of the university since 1942 In 1953 he became honorary director of the Medical Research Council's betatron research unit He was elected a fellow of the Royal College of Surgeons of England in 1948, and he was appointed C B E in 1950

The university has instituted a chair of preventive dentistry to which the council has appointed Mr J L Hardwick, M D S, who has held a readership in dental surgery in the University of Birmingham since 1952

University of Sheffield

The following appointments have been made

Dr Margaret M Platts, lecturer in medicine, Dr H A Salmon, assistant lecturer in physiology, Dr J D Howard and Dr O H Simms, part-time instructors in anæsthetics

International Symposium on Allergy

This symposium, organised by the European Academy of Allergy in collaboration with the Spanish Society of Allergy, will be held in Barcelona on June 3 and 4 Further particulars may be had from the secretary, Mr Camps, Academia de Ciencias Medicas, Via Layetana 31, Barcelona 3, Spain

Toxic Sprays Study Group

Dr J M. Barnes, Dr Donald Hunter, and Prof W L M Perry have been appointed members of this group which has been set up by the Minister for Science, the Minister of Agriculture, Fisheries, and Food, the Secretary of State for Scotland, and the Minister of Health

Expenditure on the National Health Service

The Civil Vote on Account for 1960–61 shows estimated net expenditure on the National Health Service as £519,172,485 in England and Wales, compared with £501,124,100 in the present financial year, and as £64,332,850 in Scotland, compared with £61,617,555 in the present year (1960–61, Vote on Account Civil Estimates H M Stationery Office 6*d*)

Social Security Agreements with Denmark and Finland

The reciprocal social security agreements which the United Kingdom concluded last July and August with Finland and Denmark have been ratified, and both will come into force on March 1

The agreements cover benefits provided by the schemes of national insurance, industrial-injuries insurance, and family allowances in this country and the corresponding benefits in Denmark and Finland

International Course on Lyophilisation

The Association des Cours Internationaux de Lyophilisation will run a second international course at Lyons from Aug 29 to Sept 9 Like the first international course, which was held in 1958, the meeting will be sponsored by the International Institute of Refrigeration and the International Association of the Societies of Microbiology Teaching will be in English and French and the programme includes lectures, technical demonstrations, and discussions Dr A. S Parkes will give the opening lecture Further particulars may be had from Dr L R Rey, Laboratoire de Physiologie, École Normale Superieure, 24, rue Lhomond, Paris, 5e, France

[1] 40th annual report (1958-59) of the Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia

A New Veterinary Journal

The rapid advance of veterinary research has led the British Veterinary Association to start a new quarterly journal entitled *Research in Veterinary Science.* Contributors and subscribers, at home and overseas, are asked to note that manuscripts should be sent to the scientific editor, 7, Mansfield Street, London, W.1, and annual subscriptions (90s. for non-members and 60s. for members) to Blackwell Scientific Publications, Ltd., 24, Broad Street, Oxford.

Mr. Derek Walker-Smith, the Minister of Health, has appointed Mr. B. R. Rayner to be his assistant private secretary

A refresher course for general practitioners will be held at Joyce Green Hospital, Dartford, Kent, at 3 P.M. on Fridays from April 22 to July 1. Further particulars may be had from Dr. J. C. Hogarth, West Hill Hospital, Dartford

The Hospital for Sick Children, Great Ormond Street, London, W.C.1, has prepared a brochure, *Welcome to Hospital,* which it is proposed to send to parents when arrangements are being made to admit a small patient.

The Royal National Mission to Deep Sea Fishermen sends bundles of magazines aboard vessels before they leave port. These are always eagerly read on the voyage no matter what the date. A doctor has lately sent a bundle of discards from his waiting-room and the Mission wonders whether others would be willing to follow their colleague's example. Bundles should be sent direct to the Mission Institutes R.N.M.D.S.F., Goulton Street, Hull; or R.N.M.D.S.F., 1, Charles Street, Milford Haven

be more careful in finding his way through the Alice-in-Wonderland regulations of the N H S

The latest of these oddities to come to my notice is the requiring of a family practitioner to certify a domiciliary consultation to the regional board " That a Consultant has seen a ' bona fides ' residential patient in a nursing home "

In other words, the regional board are requiring me, who is not employed by them, to give a certificate to their accountants " that Dr Physic, F R C P , is an honest man who is not bilking them " How did the Royal Colleges allow this monstrous insult to their members to be perpetrated! Why do the accountants of the regional board need the written word of a " bottom-rung " G P in addition to that of their own bona-fide top-rung employees—the consultants ? The wood of N H S administration is indeed delightfully Tulgey!

R HOWARD

CHILDREN IN POINTED SHOES

SIR,—So long as mothers wear deforming shoes, their daughters will crave to wear them also Why women want to wear them is a matter for conjecture Probably the explanation is their desire to appear as rich and leisured women, a motivation similar to that of Chinese ladies in past times who cultivated enormous fingernails

Bridlington

P D H CHAPMAN

PREVENTION AND TREATMENT OF BEDSORES BY SILICONE CREAM

SIR,—I should like to comment on the statement by Dr Kendall (Feb 27) that a silicone cream containing dienoestrol " is excellent for the prevention of sores when the skin becomes red at the pressure points (and) for superficial bedsores "

The value of local treatment in the prevention of pressure sores has been overemphasised, because of the generally held belief that the essential pathology of a pressure sore is an ischæmic necrosis which initially involves the skin, and may then progress to successively involve the subcutaneous tissues and muscle Husain[1] has shown that in an area subjected to pressure there is considerable necrosis of muscle even at a stage where the only clinical finding is erythema of the skin I have had histological sections made from similar pressure " sores " and these have shown marked muscle necrosis and have confirmed Husain's findings

The basic cause of a pressure sore is, of course, a reduction in the blood-supply to the tissues of the compressed area Various factors influence the length of time that ischæmia must be maintained to cause necrosis, but it is probably as little as four hours Skin, fat, and muscle possess different degrees of resistance to ischæmia, muscle being less resistant than skin or fat It is often with surprise that, on removing a superficial layer of necrotic tissue, one finds an enormous cavity going down to bone In some pressure sores a small blister develops and when the skin is removed the underlying tissues may appear healthy Only too often it is assumed that what is required is some local application to enable the lesion to re-epithelialise and then all will be well What in fact is required is relief of pressure Local applications are a useful adjunct and no more The same may be said for a pressure area which shows no more than local erythema of the skin

I have no wish to minimise the importance of care of the skin My object is to appeal for reorientation of ideas on pressure sores Ideas are never without influence on practice If the initial injury is held to be localised to the skin, attention and treatment will be focused here, but if it is conceded that necrosis develops in the muscle at an early stage, the application of ointments or spirit to the skin will be seen to be of secondary importance Turning a patient off his pressure areas in order to apply ointment or spirit to the skin is probably of more importance than the intrinsic value of the local application

TREATMENT OF INFECTIONS IN HOSPITAL

SIR,—I cannot let Dr Everley Jones' letter of Feb 13 go unanswered He asks is the increase in streptococcal infections widespread ? As a pædiatrician, no doubt this comes as a surprise, but to workers in infectious diseases hospitals this is no new thing

Notification of scarlet fever has been used as an index to the incidence of streptococcal infections for many years The annual report of the Ministry of Health for 1958, published in November, 1959, states that the total number of corrected notifications of this disease has been higher than it has been since 1954 The exact annual figures are 1954, 43,026, 1955, 32,619, 1956, 33,103, 1957, 29,547, 1958, 38,853

With regard to antibiotics and immunity, I would say that the use—especially if indiscriminate—of penicillin or any other antibiotic, mitigates against the establishment of firm immunity by killing off responsible organisms, either totally or partially before adequate antibody stimulation can be developed

In other words, widespread use of antibiotics *might* well provide an increase of infection rather than the reverse, including in the case of the streptococcus the survival of type-12 strain whose nephrogenic properties have been well established

Surely the only reliable method of reducing its incidence would be an actively immunising prophylactic similar to the toxoids of diphtheria and tetanus rather than killed vaccines As far as I am aware the biological difficulties associated with the isolation of such an agent seem at present—*unfortunately*—to be insuperable I would say that few, if any, authorities still recommend the use of prophylactic scarlatinal toxin because it is troublesome to use and its indications are limited to this condition

DIURETIC EFFECT OF SPIROLACTONE SC-9420

SIR,—The important observations of Dr Cejka and his colleagues (Feb 6) on the diuretic effect of SC-9420 (' Aldactone ') over a 9-day period in a patient with heart-disease necessarily failed to emphasise the clinical significance of this compound, because of the brevity of their trial Our experiences[1] in 8 patients with cirrhosis and refractory ascites, involving 155 days of hospital treatment with the drug after appropriate control periods, showed a remarkable response in every case

Prior to therapy, sodium excretion was less than 4 mEq in 24 hours, and neither weight-loss nor a negative sodium balance could be induced by a low-sodium diet or the use of mercurial diuretics, chlorothiazide, and/or prednisone Aldactone alone had a weak but definite action on body-weight and sodium excretion, but the greatest effect followed the use of standard diuretics (which had previously been ineffective) in conjunction with aldactone On this regime, weight-losses in individual patients of up to $5\frac{1}{2}$ lb daily occurred, and these were associated with 24-hour sodium urinary excretions of up to 337 mEq Subsequent studies (>200 patient-days) have confirmed the efficacy of the drug, and no toxic effect has been observed

Besides indicating that " resistance " to standard treatment in such patients is to a great extent the result of hyperaldosteronism, which could in part be a response to therapy with sodium restriction and diuretics, rather than a progressive failure of hepatic function, aldactone treatment may in most, if not all, instances replace the unsatisfactory treatment currently available. This includes the major and unpredictable operations of bilateral adrenalectomy[2] or portacaval anastomosis, the debilitating routine of repeated paracentesis, and the use of amphenone,[3] which is too toxic for routine purposes, or a spirolactone derivative which involves multiple injections.[4] Moreover, long-term studies suggest that aldactone will permit less rigorous restriction of sodium in the diet in patients with ascites.[1] The drug has two disadvantages, the first is a delay of up to 2 weeks before the clinical response is obvious, and the second, a more important consideration, is its present cost.

AUTOTRANSFUSION IN RUPTURED ECTOPIC GESTATION

SIR,—As one of the first people to write on the subject of blood reinfusion in hæmoperitoneum,[5] I beg your permission to add some further points.

The blood in the peritoneal cavity is very valuable, because after a few hours it becomes "packed-cell" blood. I have found counts up to 8 million per c.mm due to absorption of the fluid elements by the peritoneum.

I would not go so far as Professor Chassar Moir (Feb 27) in using blood that has been long effused. After blood has been forty-eight hours in the peritoneal sac it is not infrequent for staphylococci (especially the albus variety) or *Escherichia coli* to find their way into it, and in the publication I mention I quoted a case in which the patient had a temperature of 99.2°F forty-eight hours after the acute rupture and before operation. Reinfusion was not done, but eleven days after operation posterior colpotomy was needed to drain a large pelvic collection of foul infected blood. A sign that the blood is unsuitable for reinfusion is that it changes colour to a brownish purple tint.

The best baler is a coffee cup. Three or four layers of gauze should be put over the mouth of the receiving vessel and the gauze soaked in 3.8% sodium citrate solution before starting to filter the blood. One must be careful not to allow antiseptic lotions to drip from the gloves into the abdomen or the container. I used the technique successfully in several cases of ruptured spleen during the war and have used it in ectopic gestation over the past thirty years without any untoward effects.

Newcastle upon Tyne

FRANK STABLER

BRETYLIUM TOSYLATE IN THE TREATMENT OF HYPERTENSION

SIR,—In their letter of Feb 13 Dr Turner and Dr Lowther drew attention to some of the side-effects they had encountered. In particular they mentioned that 6 patients had complained of weakness, and commented that they had no evidence that it was due to actual muscular paresis.

Boura and Green,[6] working with the rat-diaphragm/phrenic nerve preparation, were able to demonstrate complete abolition of contractions in response to nerve stimulation with 400 mg per ml of bretylium in the organ bath, whereas the sensitivity of the preparation to direct muscle stimulation remained unchanged. Topical application of bretylium to the nerve trunk did not depress conduction, indicating that the block was at or near to the neuromuscular junction. In addition, with cats anæsthetised with chloralose they were able to produce respiratory paralysis and inhibition of the response of the gastrocnemius to indirect stimulation with intravenous doses of 15–30 mg per kg, direct muscle stimulation being unaffected. In monkeys doses of 50 mg per kg of bretylium produced ptosis and a diminution in muscular effort.

Boura and Green concluded from their experimental work in animals that neuromuscular block seemed to be the main toxic effect of the drug, and it seems reasonable to suppose that the same effect may be seen in man, especially when doses of 3600 mg daily are approached.

P D MULCAHY

BRONCHOGRAPHY

SIR,—I read with interest the article by Dr Smith and his colleagues last week. The technique used at Sully Hospital is essentially similar to that described by myself,[1] but is more complex and in the long run must be more time-consuming.

In a series of some 50 bilateral bronchograms that I performed at the London Chest Hospital Country Branch in 1955, I found it possible to dispense entirely with all local anæsthetics, except for the 2% lignocaine ointment smeared on the Jacques catheter, and this was used mainly for its lubricant properties. Laryngoscopy was also quite unnecessary, and with practice a rubber catheter could invariably be passed easily into the larynx, provided the tongue was pulled well forwards, with the patient sitting in the erect position.

I used an oily solution of 'Dionosil' (propyliodone) which gave excellent contrast and no alveolar filling, clearing usually taking place within 24 hours.

The patients subjected to this technique, many of whom had undergone bronchography by other methods, were interviewed afterwards. They were unanimously impressed by its speed, and by the absence of discomfort.

Sutton, Surrey

J C BARKER

EARLY TREATMENT OF STOVE-IN CHEST

SIR,—I should like to comment briefly on the most instructive article by Mr Barrett (Feb 6).

I think a point which Mr Barrett might well have made is that an early electrocardiograph is almost indispensable to the full assessment of cardiorespiratory function in these cases. I have been asked to see three cases during the past year which illustrate this contention.

The first, a young man of 33 years, after a motor-car accident had multiple rib fractures, massive left-sided intrapulmonary contusion, and a retroperitoneal hæmatoma. Two days after the accident his E.C.G. suggested the presence of anterolateral epicardial damage, presumably due to direct contusion. Adequate doses of a digitalis preparation seemed very helpful in tiding him over the next few difficult days.

In an elderly man, the E.C.G. taken on the day after the accident showed evidence of extensive anterior cardiac infarction involving the entire thickness of the ventricular wall. It was impossible to tell whether the infarction arose from direct trauma, or was the result of the initial shock and hypotension of the accident. I felt that anticoagulants were contraindicated, and he made a slow and somewhat halting recovery.

A robust man of 65 sustained bilateral multiple rib fractures, and X-ray appearances suggested bilateral intrapulmonary contusion. I saw him two days after the accident, when he was still shocked, hypotensive, and cyanosed. E.C.G. suggested posterior ischæmia and there was a sinus tachycardia of 160 per min. Rapid digitalisation reduced the apex-rate to 110 within twelve hours, with considerable immediate improvement in his general condition. Three days later the E.C.G. had reverted to normal, except for a digitalis effect. This rapid reversal of pattern indicates that the E.C.G. changes were due to acute pulmonary hypertension rather than myocardial contusion or ischæmia, the pulmonary hypertension being brought about by a reflex pulmonary vasoconstriction, as suggested by Mr Barrett.

ORAL HYPOGLYCÆMIC AGENTS

SIR,—I read with interest your leading article [1] on this subject Regarding biguanides, it mentions only the American works about phenethylbiguanide May I be permitted to quote the extensive experimental and clinical work which shows the interest and clinical advantage of N N-dimethylbiguanide hydrochloride?

(1) It is particularly well tolerated by the digestive tract, and, if given in divided doses after meals, the digestive side-effects stop the treatment in not more than 1–4% of cases (compared with 15–40% mentioned in the articles on phenethylbiguanide)

(2) Of the many thousands of patients treated with N N-dimethylbiguanide without insulin, there have been no reports of ketosis On the contrary some antiketogenic activity was noted

(3) Trials are being conducted in Britain at present The very extensive work done in France shows a wide range of activity of N N-dimethylbiguanide in every sort of diabetes Especially in brittle diabetes, the fluctuations in blood-glucose are suppressed It is often possible to cut insulin in insulin-dependent diabetes Some action was noted even in diabetic children The proportion of overall successes is greater than with the sulphonamides

(4) Three years' extensive experimental work on animals preceded clinical use of N N-dimethylbiguanide, and showed that the drug had negligible toxic effects in therapeutic dosage (calculated on a weight basis)

In man, there was no case of kidney, liver, or blood damage, even after over two years' treatment in more than 10,000 patients The drug was given without inconvenience to diabetics with sulphonamide jaundice, and to patients with mild azotæmia

Argenteuil, Seine-et-Oise JEAN STERNE

CONTROL OF ANTICOAGULANT THERAPY

SIR,—Dr Laurie (Jan 23) concludes that the price of the thrombotest reagent "if sustained, renders an otherwise quite admirable preparation uneconomical for general use"

The original technique requires 0 5 ml of reagent and 0 10 ml of blood The price is then about 1*s* 6*d* per test This technique was devised to secure maximal accuracy and reliability in inexperienced hands However, we have recently found that the average technician after some training obtains the same accuracy by using only 0 25 ml of the reagent and 0 05 ml of blood Figs 1 and 2 give the results of simultaneous estimations, using 0 5 ml and 0 25 ml of reagent with both capillary and venous blood The clotting-times agree closely, and the test can therefore safely be used with only half the volume of reagent which was originally suggested

Besides bringing the price per test down to about 9*d*, the new technique also has the advantage of facilitating the collecting of the capillary blood samples because of the reduced volume Our standard interval between controls of patients on long-term anticoagulant therapy is 4 weeks The cost of thrombotest reagent for one year's treatment consequently is 9*s*

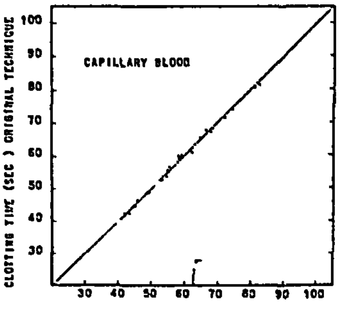

Fig 1—Comparison of techniques with capillary blood

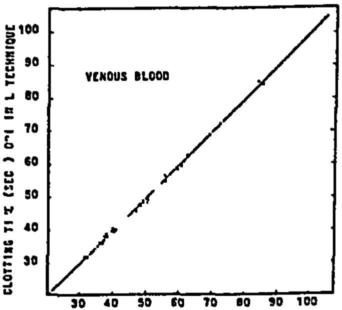

Fig 2—Comparison of techniques with venous blood

Rikshospitalet, Oslo P A OWREN

MAGNESIUM DEFICIENCY FOLLOWING MASSIVE INTESTINAL RESECTION

SIR,—Dr Fletcher and his colleagues (March 5) have made the interesting observation that the serum-magnesium level was subnormal in a patient subjected to intestinal resection However, we are uncertain whether they are correct in assuming that the clinical response in their patient was due to treatment with magnesium

The first fæcal fat excretion of 50 g per day suggests that the patient was initially receiving considerably more than 50 g daily in the diet The fæcal fat excretion of 10 g per day *after* treatment is taken to indicate that there had been an improvement in intestinal function This conclusion is only valid if the dietary fat remained unchanged throughout the entire period of study Patients who have steatorrhœa associated with lesions of the distal small intestine—either resection or regional enteritis—often take high-fat diets in vain efforts to "fatten themselves up" Such patients may improve dramatically when treated with a low-fat (less than 50 g) and high-protein diet It is therefore necessary to inquire how much dietary fat was given to the interesting patient described by Dr Fletcher and his colleagues, and whether fat ingestion had been excessive before admission to hospital

C C BOOTH
A E READ

POSTCOITAL EXAMINATION OF SEMEN

SIR,—My purpose in questioning [1] the ultimate usefulness of the usual methods of semen examination was to stimulate discussion which might answer my questions am I doing the best thing for my patients by adhering to the postcoital urethral specimen, or would I achieve higher pregnancy rates by changing over to masturbation? Dr Davidson (Jan 2) is deeply perturbed by my pessimistic attitude, which must seem to him reactionary and obscurantist

Seminology always appears to me a sledgehammer type of investigation While cytologists can give useful information from a few desquamated cells, and hæmatologists can make a diagnosis by micromethods instead of demanding a pint of blood, the seminologist must still have the whole sorry ejaculate If the hæmatologists are willing to abandon the traditional absolute indices as being of little value, might we not expect a similar agonised reappraisal on the part of the seminologists?

I should be grateful for Dr Davidson's references to successful treatment of subfertile men I always read such papers eagerly but have never yet been convinced, and this is not merely for the sake of scepticism but mainly to serve the patient better by discovering where lies the truth One reference from Farris,[2] a pre-eminent seminologist, will suffice to restate my case Occasionally his zeal makes our eyebrows rise and our hair stand on end In one experiment (p 101) he records the seminal examinations of one man who masturbated on each of 20 consecutive days While this is doubtless a remarkable achievement on the part of both doctor and patient, it served only to confirm what is common knowledge—namely, that the sperm-count is subject to considerable variation, and therefore higher counts should not necessarily be accepted as therapeutic successes In another test (p 48) he made a study of the mechanics of masturbation, scientifically checked by stop-watches Even this experienced investigator could find no way of improving the semen sample apart from "pituitary irradiation, the partitioned ejaculate, and centrifugation" (p 161), and as for facilitating conception he finds "there is little hope for the subfertile group" (p 198)

---

[1] *Lancet* 1959 ii, 1129

[1] *Lancet* 1959, ii, 974
[2] Farris, E J Human Fertility New York, 1950

Dr Davidson describes very generously his investigations which are much more precise and thorough than my more homely, though happier, methods, but I searched in vain for the evidence, drawn from his enviable series of 12,000 husbands, that he is able to report more successful pregnancies than those who favour a more subtle approach This essential information he fails to give

Auckland, New Zealand H P DUNN

REDUCTION OF SPUTUM VISCOSITY IN CHRONIC BRONCHITIS

SIR,—As Dr Blanshard observes (March 5) there is often a diurnal variation in sputum viscosity, that produced overnight being more viscid than that expectorated during the day There is also often considerable daily variation in the viscosity of morning specimens[1] I found that the viscosity of sputum produced by chronic bronchitics in hospital at hourly intervals for three hours during the afternoon varied by less than 5% This period was chosen, therefore, for the experiments when it was found that after the aerosol inhalation of a water mist for one hour, there was a mean reduction of sputum viscosity of 21 5%[2]

HIGH PLASMA-IRON IN PORPHYRIA

SIR,—The observation by Dr Hathorn and Dr Lamont (Jan 30) of hypersideræmia in 15 of 23 cases of porphyria in the Durban Bantu is of some interest We have observed significantly raised levels of plasma-iron in 7 of 12 Bantu subjects with symptomatic porphyria cutanea tarda (P C T)

Liver biopsy specimens were taken in 8, and 6 of these showed heavy deposits of hæmosiderin, while in 2 moderate amounts were present. Radioiron studies, in which the plasma iron turnover and red-cell utilisation were measured, gave results compatible with iron overload in 5 out of 12 subjects

In a further study, liver biopsies were carried out on 25 Bantu subjects with symptomatic P C.T In 22, varying degrees of siderosis were found and in 8 cirrhosis was present

The interpretation of these results is difficult since siderosis occurs in approximately 80% of Bantu adults It should be noted, however, that there are several reports in the literature in which hypersideræmia[3,4] or excessive iron deposits in the liver[5–7] have been noted in patients with P C T These reports from regions where siderosis is not common, suggest that the association between porphyria and siderosis may be significant.

The frequency of symptomatic P C T in the Bantu is, however, probably not directly related to iron overload, since it can occur in the absence of significant siderosis On the other hand, it is quite possible that the derangement in porphyrin metabolism may be the result of some unknown agent absorbed with the iron, or alternatively, iron overload may alter the susceptibility of the individual to noxious stimuli

In white subjects suffering from the hereditary disease, porphyria variegata (mixed porphyria), characteristic changes in iron metabolism occur during acute abdominal episodes A study of 12 subjects has shown that the plasma-iron level rises and the percentage utilisation of radioiron for red-cell production is reduced Although these findings can be interpreted in several ways, they raise the possibility that the marrow uptake of iron is impaired during acute phases of the condition

ENZYME-DEFICIENCY HÆMOLYTIC ANÆMIAS

SIR,—The paper by Dr Houston and Dr Barlow,[1] dealing with a case of acute hæmolytic anæmia secondary to administration of phenacetin, prompts us to comment on the present status of knowledge about the hæmolytic anæmias induced by chemical compounds

Clinical observation and biochemical studies of erythrocytes have enabled us to recognise a complex enzyme abnormality of red cells as a fundamental predisposing factor in many acute hæmolytic anæmias induced by pharmacological or vegetable agents

The main feature of this abnormality is a deficiency of glucose-6-phosphate-dehydrogenase,[2] which seems to be inherited through a semi-dominant sex-linked gene, but it is also revealed by the low erythrocyte content of glutathione[3] and by the extreme susceptibility of glutathione to in-vitro oxidation by several compounds, of which acetylphenylhydrazine is the best example[4] In the same red cells a compensatory hyperactivity of some enzymes of the glycolytic anaerobic pathway has been also demonstrated[5] Patients affected by this abnormality generally belong to particular ethnic groups and, more specifically, to some peoples of the Mediterranean area (Sardinia, Spain, Greece, Israel) or to the Negro race

On the basis of such constitutional predisposition, not only phenacetin, but a great number of chemical substances, in pharmacological or industrial use or of a vegetable nature, seem able to provoke a violent crisis,[6] often with hæmoglobinuria.

In this group we must include certain aniline derivatives, such as sulphanilamide and its own derivatives (sulphapyridine, sulphapyrimidine, sulphathiazole, sulfoxone, thiazosulphone, &c.),[7] acetanilide, phenacetin,[8] antipyrin, probenecid, *p*-aminosalicylic acid, substances with a nitro group in their molecule (nitrofurans, chloramphenicol,[9] and trinitrotoluene[10]), naphthalene and its quinone derivatives, quinine and quinidine[11] and 8-aminoquinoline derivatives (primaquine, pamaquin, &c.)[12,13] Hæmolytic factors also seem to be present in several vegetable organisms, since the ingestion of the fruits or the inhalation of the pollen from *Vicia faba*, *Pisum sativum*, *Hydrargyris fœtida*, &c., have been shown to induce an acute hæmolytic episode[14]

As the red-cell defect in glucose-6-phosphate-dehydrogenase seems to be the determining factor in the onset of acute hæmolysis, we thought it advisable to group all these anæmias under the title "enzyme-deficiency hæmolytic anæmias"

IDENTIFICATION OF PROPRIETARY DRUGS

SIR,—About 350 to 400 new proprietary drugs are appearing in this country annually, our card-index collection of these now numbers some 2500 collected over six years

Many of these have identical chemical compositions and hence a common approved name Many doctors may not have the time to study the officially approved lists, in such cases, we would be very pleased, as a free service to the medical profession, to give full information of synonyms, official and approved names, and approved international names where applicable, to enable these gentlemen to find their way through this jungle

A PROPOSED GENETIC THEORY FOR THE PATHOGENESIS OF CERTAIN CONGENITAL GONADAL DEFECTS

SIR,—The recent reports[1,2] of 45-chromosome individuals (XO, chromatin-negative) with Turner's syndrome (gonadal aplasia, dwarfism, and congenital somatic abnormalities) suggest that the lacking sex chromosome (X or Y) contains genes which serve to create a balance for normal development in these categories in the presence of the normal X chromosome and autosomal genes We postulate that chromatin-positive patients (presumably XX) with the complete triad of Turner's syndrome have a chromosomal aberration (e g, deletion) of a portion of one X chromosome to account for the lack of sex, stature, and somatic balance manifested in these patients Chromatin-positive individuals with only gonadal aplasia and dwarfism may have a smaller X chromosome aberration affecting only the sex and stature genes, leaving the somatic genes intact

With the sex genes of one X chromosome partially lost, we may explain those chromatin-positive individuals with incomplete forms of gonadal dysgenesis who have nests of primordial follicles or hypoplastic ovaries (with or without the other stigmata of Turner's syndrome, depending upon whether the stature and somatic genes are also lost) The genes for gonadal development and stature are probably closely associated on the sex chromosome since individuals with gonadal dysgenesis who are not stunted in growth are reported rarely and we have not been able to find any reported cases of gonadal aplasia associated with multiple congenital anomalies that did not have dwarfism

A chromatin-positive female with only defective ovarian structure and function has been described with 47 chromosomes (XXX)[3] The impaired balance of sex genes in this XXX combination, produced by non-disjunction of the sex chromosomes, probably accounts for the defective ovarian development in this patient Likewise the impaired sex gene balance in the XXY combination, recently reported in chromatin-positive males with Klinefelter's syndrome,[4,5] may account for the dysgenetic testes found in these individuals

A phenotypic female with an XY chromosomal complement (chromatin-negative) has recently been reported as an instance of pure gonadal dysgenesis on the basis of primary amenorrhœa and high urinary gonadotrophins[6] We postulate the presence of a chromosomal aberration involving the sex genes of the Y chromosome (or the sex genes of the X chromosome if they are found to be needed for appropriate genetic balance with the Y sex genes to form normal testes) to explain this phenomenon Turner's syndrome in males (presumably an XY chromosome combination) may be explained by a similar chromosomal aberration affecting the stature and somatic genes of one sex chromosome with only a partial loss of sex genes, so that hypoplastic or undescended testes are formed which are still capable of bringing about male differentiation Male pseudohermaphroditism may be due to a hereditary mutation of the maternal X chromosome which affects or modifies the balance with the Y chromosome sex genes and possibly the autosomal genes after fertilisation Variable degrees of altered expressivity of the sex genes of the Y chromosome due to differing chromosomal aberrations (deletion, inversion, translocation, crossover) or gene mutations on the X or Y chromosome may be involved in those chromatin-negative males with tubular fibrosis, germinal aplasia, congenital anorchia, cryptorchidism, and low fertility when these have a genetic basis

The Y chromosome has recently been shown to be the bearer of male fertility in *Drosophila busckii*,[7] and of male determining factors in the mouse[8] We postulate that the formation of testicular elements in the human is dependent upon the presence of a *functional* Y chromosome or the *functional* sex gene portion of a Y chromosome The development of ovaries would be dependent upon the presence of the *functional* sex genes of two X chromosomes either in the absence of Y sex genes or in the presence of severely altered Y sex genes We explain the gonadal defects found in the true hermaphrodite on the basis of crossover or translocation processes affecting the sex genes of the X and Y chromosome at the time of their terminal association in the primary spermatocyte With these phenomena, both XX and XY offspring could inherit specific genes of the opposite sex to produce effects upon the fœtal gonads which depend upon the amount of crossover or translocation of sex genes, and upon which abnormal sex chromosome eventually fertilises the ovum Two chromatin-positive true lateral hermaphrodites have been described with an XX chromosome complement (46 chromosomes)[9,10] We postulate that the paternal X chromosome donated Y sex genes, obtained by crossover or translocation, which induced the formation of a testicle Chromatin-negative individuals[11,12] (presumably XY) have been reported with biopsy studies revealing normal ovarian tissue These patients may have been examples of the paternal X chromosome sex genes completely replacing the Y chromosome sex genes by the crossover phenomenon before fertilisation Altered degrees of expressivity of the sex genes on the abnormal paternal X or Y chromosome may account for those chromatin-negative or chromatin-positive individuals with gonadal dysgenesis who have vestigial cortical (ovarian) and medullary (testicular) remnants (a lesser degree of differentiation of the ovotestis)

We suggest that there are closely associated, but separate, sex genes on the X and Y chromosome which influence the development of the gonad on each side An example of a complete crossover between the X and Y chromosome involving the gene(s) of one side only may be the true lateral hermaphrodite with an ovary or testis on the side influenced by the crossover phenomenon and the opposite gonad being induced by the normal gene(s) remaining on the X or Y chromosome If a partial crossover or a translocation affects the genes involved with one gonadal site then one might have an ovotestis associated with either an ovary or testis on the other side If a partial crossover or a translocation affects the genes involved with both gonads then ovotestes would appear bilaterally If a deletion of a portion of the chromosome involved in the

crossover occurs, the individual might have an ovotestis on one side and no gonad on the other

We have used basic genetic principles in an attempt to explain certain human gonadal and somatic defects that have been proven or postulated to be on a sex chromosome basis We hope that this unified theory may stimulate an approach to the study and understanding of these disorders in the future

A more detailed presentation of this concept will be published elsewhere

KARYOTYPES IN KLINEFELTER'S AND TURNER'S SYNDROME

SIR,—Ohno et al[1] have recently reported that one but not the other X chromosome is heteropyknotic in the female rat They point out that the X chromosome derived from the father would form the sex-chromatin body since males, having X chromosomes of maternal origin, are sex-chromatin-negative If such condition obtains in man one might infer the possibility of unreported aberrant karyotypes

If some cases of "false" (sex-chromatin-negative) Klinefelter's syndrome and of sex-chromatin-positive Turner's syndrome are phenotypically similar to their "true" counterparts, they may have similar karyotypes If sex-chromatin-positive Turner's syndrome has only 45 chromosomes, the single X would be of paternal origin Conversely "false" Klinefelter's syndrome might have an XXY complement in which both X chromosomes are a maternal contribution

Pursuing these assumptions, let us consider the possibilities should non-disjunction occur at either first or second meiosis in mother or father Both the reported 47 chromosome XXY Klinefelter's and the 45 chromosome haplo-X Turner's could result from non-disjunction of the sex chromosomes at the first meiotic division in the father This would give XY gametes and gametes having no sex chromosome The former could lead to the sex-chromatin-positive Klinefelter's syndrome while the latter deficient gametes could give rise to sex-chromatin-negative Turner's syndrome, as pointed out by Ford et al[2] Non-disjunction at first meiosis in the mother might give rise to ova having two X chromosomes or to ova having none The former ova could eventuate in sex-chromatin-negative Klinefelter's syndrome or in triplo-X females having one sex-chromatin body per nucleus The deficient ova might give rise to sex-chromatin-positive Turner's syndrome having a single X chromosome, paternal in origin (The other possibility, with Y as the only sex chromosome, we might assume, with Tjio et al[3], to be lethal)

Non-disjunction at the second meiotic division in the mother does not add to the hitherto described possibilities, but in the father it could result in diplo-X and diplo-Y gametes The former could give rise to triplo-X females having two sex-chromatin bodies per nucleus Perhaps this is the variety reported by Jacobs et al[4] The diplo-Y gamete could result in the hypothetical karyotype mentioned in your recent editorial[5]

One case of euploid sex-chromatin-negative Klinefelter's syndrome has been reported[2] It would be interesting to hear reports on the karyotypes of further cases of "false" Klinefelter's syndrome and of sex-chromatin-positive Turner's syndrome

TELEVISION HAZARDS

SIR,—Your annotation of Dec 26 presents an informative review of some of the disorders that have been reported to result from television viewing In order that the list be as complete as possible, I am taking the liberty of providing information on several more conditions which have been attributed to the television pastime, and have been reported in the medical literature

Sprofkin[1] has described the occurrence of a compression neuropathy affecting the common peroneal nerve and its branches in relation both to therapeutic weight reduction and to the prolonged inactivity of the television posture Cooper[2] has reported what he calls "television bottom", a state, essentially, of coccygodynia, resulting from extended periods of immobility before the TV screen

Several cases of suicide have been recorded in mentally unstable individuals after viewing television productions dealing with medical topics[3]

The impact of TV crime shows on juvenile behaviour is already too well documented to require other than passing mention

TREATMENT OF ADVANCED CARCINOMA OF BREAST

SIR,—We hope our dogmatic statement (Jan 16) "operation is necessary because X-ray castration does not completely stop ovarian function" was not too misleading We prefer oophorectomy for its rapidity of action and because it must necessarily remove one source of œstrogenic hormones X-ray castration can, of course, be effective, and in certain cases may be the method of choice However, it can fail, particularly if the dose is on the low side

Kottmeier[4] found active corpora lutea at laparotomy after radiation sterilisation He has also found that there are greater changes in the FSH levels excreted in the urine, in patients who have had an X-ray menopause than in those who have had a radium menopause. This suggests that the level of the ovarian dose of radiation determines the decrease in endocrine function.

Axel Westman[5] studied the problem in rats and found that an X-ray dose of 3000r is needed to cause histological destruction of the ovary If 1500r is used, ova and primordial follicles are destroyed, but corpora lutea and interstitial cells are not affected. It is likely that the stromal cells and thecal cells are responsible for some of the relevant hormone production, and Jessiman and Moore,[6] in support of this, refer to "cortical stromal hyperplasia" in patients with carcinoma of the breast These stromal cells need a high dose of radiation to inactivate them, and we feel it is more disturbing to the patient to treat the ovaries to this high level of radiation than to remove them

In our own series of 267 cases given X-ray menopauses for menorrhagia, we have 38 failures, using a standard technique which delivers 700r to the pelvis in 2 treatments in five days These are failures to control bleeding, and in 24 cases they could be explained by fibroids or other associated conditions However, in 14 cases there appeared to be no explanation except that the ovarian cells in these patients were less sensitive to irradiation

We realise there is no controlled clinical trial of X-ray castration versus surgical castration in treatment of advanced carcinoma of the breast In the present state

SERUM QUININE OXIDASE

SIR,—Referring to the communications by Roman and Dulmanis [1] concerning the results with Baier's quinine-oxidase activity test for the differential diagnosis of obstructive jaundice and hepatocellular damage,[2] we should like to point out that this test has nothing to do with the determination of the quinine-oxidase activity Using pure water, instead of the aqueous quinine hydrochloride solution, the same results are obtained The effect is due only to protein precipitation by dilution with water Details have been published elsewhere [3]

"CRISIS IN NURSING"

SIR,—The other day whilst turning out some files I came across a copy of a letter which I sent ten years ago to the then Minister of Health

Apart from the date it needs no alteration

29th March, 1949

Dear Mr Bevan,

I have long advocated a plan which would help to solve the problem of shortage of nurses and which I should like to put before you

The essence of the plan is that nurses should not be drafted from the wards to assist in the operating theatre, but that such assistance should be performed by a specially trained staff just as in the physiotherapy or radiology departments

Many nurses are peculiarly fitted by temperament and inclination for ward work and dislike having to leave the ward, with its human contacts and human problems, to work in the impersonal atmosphere of the theatre Such nurses never make good theatre assistants because their hearts are not in their work

Nevertheless, theatre work has a special appeal to a different type of girl (as the advertisements designed to attract girls to the nursing profession attest) and many of these potential recruits are discouraged by the thought that to fulfil their ambition to assist at operations, they will have to go through what to them is the drudgery of the wards with its bedpans and sluices

As a result of my army experience, I am convinced that such a general training in nursing is not essential as a preliminary for theatre work It was possible during the war to train a keen young man into a first-class theatre assistant in under a year

I shall not here go into more details, but I feel sure that such a plan is practicable although it will raise tremendous opposition from the diehards, and I am sure too that it would attract sufficient recruits for theatre work to relieve hundreds of nurses for work in the wards, which in many instances is more congenial to them As a surgeon I am especially interested in the efficiency of the theatre team and by making this part of the medical service a special profession, I am convinced that this too will be immeasurably improved

I am, Sir,
Yours sincerely,
H J B ATKINS

The Rt Hon Aneurin Bevan, M P
Minister of Health,
Whitehall, S W 1

The only official reaction to this letter was a gentle rebuke from the authorities because it was written from the hospital which I have the privilege to serve and might on that account have been regarded as representing the views of that hospital I hasten to add therefore that so far as I know this letter does not represent the views of the Garrick Club

H J B ATKINS
Dean of the Institute
of Basic Medical Sciences

The Garrick Club,
London W C 2

ANTI-SMOKING CAMPAIGN

SIR,—May not the failure of this campaign be due to the fact that its advocates frequently talk a deal of nonsense—for example, that smoking tobacco is on "all fours with smoking opium or hashish"? I have been smoking for 40 years and have never had the slightest trouble in giving it up for a week or so—after a cold, for example After an attack of "Asiatic" influenza 2 years ago the taste and smell of tobacco became unpleasant to me, and deeply I regret it I only hope I don't lose my taste for port or claret I like them both but am not addicted to either

Buxton, Derbyshire

F A BEARN

WHAT IS A TRANQUILLISER?

SIR,—The definition by Dr Cook (Feb 27) is a bit on the sour side, is far from complete, and suggests that chlorpromazine is excluded from its application I do not presume to offer a definition, but I suggest the addition of the masking of physical signs so that physical disease may escape early recognition [1]

The earliest description in accord with our notions of what constitutes a tranquilliser which I have been able to discover is that of De Quincey [2] who, referring to opium, spoke of "subtle powers (when judiciously regulated) (1) to tranquillize all irritations of the nervous system, (2) to stimulate the capacities of enjoyment, and (3) under any call for extraordinary exertion (such as all men meet at times), to sustain through twenty-four consecutive hours the else drooping animal energies " Has it been bettered?

Gaillimh, Ireland

S UA CONCHUBHAIR

ANTIMONY DIMERCAPTOSUCCINATE IN INTESTINAL BILHARZIASIS

SIR,—In their interesting letter [3] on the suppressive management of urinary bilharziasis with antimony dimercaptosuccinate (TWSb), Dr Friedheim and his colleagues have demonstrated the promising effects of a single intramuscular dose, which have been confirmed by Friedheim and de Jongh [4] Recently a small experiment on similar lines was conducted in East Africa on the intestinal form of the disease (*Schistosoma mansoni*)

16 patients from an endemic area of *S mansoni* near Nairobi, Kenya, were divided into two groups of 8 None had received previous treatment The sole criterion was that they should be passing many viable ova, easily visible on direct stool microscopy The first group received a single intramuscular injection of TWSb The second group received two intramuscular injections on successive days Dosage was calculated on a sliding scale dependent on body-weight 15–25 kg , 300–350 mg , 26–36 kg , 350–400 mg , 37–49 kg , 400–450 mg , 50 kg and above, 500 mg The drug was given in 10% solution dissolved in sterile normal saline Fæcal examinations were carried out frequently by direct microscopy and the hatching test described by Newsome [5] 6 patients from each group of 8 were satisfactorily followed up for five to six weeks In 5 of each group, egg excretion was impaired for two to four weeks, beginning seven to ten days after administration of the drug In 1 of each group no effect on egg production was demonstrable 6 of each group (i e , all who completed follow-up) reverted to their pretreatment egg output within thirty-eight days after dosage This was confirmed by a check examination on the fortieth day

In this small experiment, the dosage of the first group was

similar to that employed by Friedheim et al. The second group received twice the dose given to the first group, but egg production was only affected for some two to four weeks. All patients had strongly positive hatching tests at thirty-eight days, whereas the *S. hæmatobium* patients of Friedheim were still not passing any viable ova at one month.

It appears that the encouraging results of suppressive management of urinary bilharziasis cannot necessarily be applied to the intestinal form of the disease. The effect of TWSb injections repeated monthly is now being studied in patients with *S. mansoni* and *S. hæmatobium* infections.

GENERALISED LYMPHADENOPATHY, BLOOD CHANGES, AND RASH ASSOCIATED WITH METHOIN

SIR,—Since the introduction of new anticonvulsants (such as phenytoin, methoin, and troxidone) there have been many reports of toxic manifestations,[1–8] the most significant reactions being hæmatological. During treatment with 5-ethylphenylhydantoin ('Nirvanol'), which was once used for rheumatic chorea, a mild lymphadenopathy was noted[9], and it is now recognised that hydantoin can cause generalised adenopathy of varying degree, mimicking clinically and pathologically a malignant lymphoma.[8 9]

Salzstein and Ackerman[10] collected from the literature 82 cases of lymphadenopathy induced by anticonvulsant drugs, particularly by methoin. The cervical nodes are often involved. The glands are often tender, and they usually first appear one to two weeks after treatment began, or may be very much later. Although lymphadenopathy may be the only toxic manifestation, it is usually associated with other reactions, such as fever, skin rashes, hæmatological changes, and liver involvement. The most characteristic feature of this lymphadenopathy is its disappearance when the drug is stopped. When biopsy was performed the nodes showed reticulum-cell hyperplasia with many mitotic figures and infiltration with eosinophils, neutrophils, plasma cells, and young lymphocytes.[10–11] Chiari[11] referred to fibrinoid necrosis.

Among changes in the blood-picture leucopenia may lead to agranulocytosis and aplastic anæmia. There is a mild leucocytosis in some cases. Lymphocytosis[12] and monocytosis[11–13] have been reported. In very many cases a significant eosinophilia was found.[10] Increase in plasma cells was noted in 2 patients, and in 2 a typical picture of lupus erythematosus developed after administration of methoin.[14]

The following case may be of interest.

A 38-year-old unmarried female was admitted to hospital because of fever, skin rashes, and lymphadenopathy. Twenty-six days before, high fever and cough developed. She was given penicillin and later chloramphenicol but the fever persisted. During the course of penicillin a generalised morbilliform rash appeared and continued despite stopping the penicillin. In the last few days of penicillin therapy a cervical lymphadenopathy was noted.

She had been in good health until the age of 23 when grand-mal seizures began. In the past six years she was treated with phenobarbitone and diphenylhydantoinate, and the attacks had disappeared. Six weeks before admission, methoin was introduced (0·2–0·3 g. daily).

On admission to hospital she was an acutely ill and mildly underdeveloped female with temperature of 37·8°C (100°F). There was a generalised scarlatiniform rash and desquamation of the hands. Several firm, indolent, freely movable lymph-nodes were found in the cervical, axillary, and inguinal regions. No other abnormal findings and no enlargement of the liver or spleen were detected. X-ray of the chest was normal. The tongue was reddened and the papillæ were atrophied. A diagnosis of idiopathic epilepsy was substantiated by electroencephalography.

Laboratory data.—Red cells 3·7 million per c.mm., hæmoglobin 10 g. per 100 ml., white cells 11,000 per c.mm. (38% neutrophils, 21% band forms, 2% monocytes, 17% eosinophils, 2% plasma cells, and 18% lymphocytes). Reticulocytes 4·5%. Hæmatocrit 40%. Platelets 280,000 per c.mm. Paul-Bunnell, direct Coombs, Widal, and brucella agglutination tests were negative.

Bone-marrow puncture showed an eosinophilic reaction (18·5% eosinophils) and plasmocytic proliferation (10·5% plasma and reticulum cells). Thymol turbidity test 17 units. Total serum-cholesterol 120 mg. per 100 ml., total serum-bilirubin 1 mg. per 100 ml., blood-urea 20 mg. per 100 ml., total serum-protein 6 g. per 100 ml. (albumin 2·4, alpha-globulin 0·12, alpha-2-globulin 0·42, beta-globulin 0·72, gamma-globulin 1·9).

A cervical lymph-node was biopsied (Prof. Besima Tarhan) and showed destruction of most of the normal architecture. A striking reticulum-cell hyperplasia was found. Some lymphoid hyperplasia and sparse plasma cells were present.

After methoin was stopped fever subsided in a few days and the rash disappeared slowly. The lymph-node enlargement subsided completely in twenty-five days. One cervical node swelled again to the size of an egg, but it disappeared in a few days with local treatment. The hæmatological findings on the thirty-second day were: white cells 9000 per c.mm. (64% neutrophils, 12% band forms, 5% eosinophils, 8% monocytes, and 11% lymphocytes). Thymol turbidity test 7 units. All symptoms disappeared and the patient is now fit, apart from occasional epileptic seizures.

Because symptoms appeared during methoin therapy and disappeared completely when it was stopped we feel convinced that methoin was the cause. Possibilities such as infectious mononucleosis, undulant fever, and lupus erythematosus were eliminated, and Hodgkin's disease and benign lymphogranulomatosis were not suggested by the histological pattern of the lymph-node and the disappearance of all symptoms.

As far as we know, only 2 instances of lymphadenopathy induced by anticonvulsant therapy and associated with plasmocytic reaction in bone-marrow have been reported[10 15] (1 with a plasmocytosis of 22%). Some authors have recorded monocytosis in toxic reactions due to hydantoin therapy.[11–13] We believe that the paucity of reported plasmocytosis in lymphadenopathy induced by anticonvulsant therapy is due to the lack of complete hæmatological investigation in the vast majority of cases.

A PORTRAIT OF Mrs. HARVEY

Prof. K. J. FRANKLIN writes:

"There used to be at Burley on the Hill a portrait in oils of Mrs. Harvey, wife of the discoverer of the circulation of the blood, but it was destroyed by fire towards the beginning of this century. I should very much like to get a description from someone who saw the picture before its destruction, even more to find a photograph or painted replica of it. I should therefore be most grateful to anyone who can and will send me information (at Broomfield, Yarnton, Oxon.)"

POSTGRADUATE CONFERENCES IN GLASGOW

For the past four years the University of Glasgow and Royal Faculty of Physicians and Surgeons have been holding a series of conferences as part of their postgraduate education programme The Kidney has been chosen as the subject of the next, which is to be held in the hall of the faculty, 242, St. Vincent Street, Glasgow, C 2, from March 30 to April 1

It will be opened by Mr Arthur Jacobs and the speakers will include Mr W F Cook, Prof Roger Warwick, Dr A M Joekes, Dr H E de Wardener, Prof A. A G Lewis, Dr M D Milne, Prof D A. K Black, Prof G M Bull, Dr J W Chambers, Dr J C Eaton, Dr F M Parsons, Dr J S Robson, Dr A C Kennedy, Dr I A Short, Dr Molly Hill, Dr G C Arneil, Dr R. H Gorrill, Sir Dugald Baird, Mr Alexander Marshall, Dr J D Williams, Prof W S Peart, Prof Clifford Wilson, Prof Ian Donald, and Dr C Dollery

There is no fee for the course There will be an informal dinner on March 31 (tickets £1) Further particulars were given in our advertisement columns last week

University of Oxford

On Feb 27 the following degrees were conferred

D M—R A Bruce
B M—D I Fry, R J Lunt

University of London

Dr J H Green, senior lecturer in physiology at Middlesex Hospital Medical School, has been appointed to the university readership in physiology tenable at that school

Triple Qualification Board of Scotland

The following have been granted the diploma of licentiate of the Royal Colleges of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow

D T M Calderwood, M R Campbell, K C Clarke, G I Cohen, David Crookenden, L C. Florin, N G Hamilton, Stella Pak-Ngor Ho, A S Jackson, Botio Kalcev, Sybil F Kinghorn, A N Kotwall, E T Nagy, W H Williams

Training in General Practice

Three further Nuffield practitioners have been appointed under this scheme (*Lancet*, Feb 6, p 343) Dr W F Webb is to be registrar to the Portsmouth Group and later trainee to Dr M Duncan, Captain P P Carter, R A M C, registrar to the Royal Hants County Hospital, Winchester, and later trainee to Dr G Swift, Flight-Lieutenant D R Burcombe registrar to the Southampton Group and later trainee to Dr D Ramsay

International Society for Tropical Dermatology

At the organisational meeting of this society in New York on Jan 25 Prof Aldo Castellani was elected president, Dr Frederick Reiss secretary-general, and Dr J Lowry Miller treasurer The inaugural meeting is to be held on May 10, at 8 P M, at the Rockefeller Institute, New York, when Professor Castellani will give an address on elephantiasis tropica and elephantiasis nostras Further particulars may be had from Dr Reiss, 870, Fifth Avenue, New York, 21, N Y

Life Insurance Medical Research Fund of Australia and New Zealand

This fund has been established to promote and assist scientific and medical research in cardiovascular function and disease Grants will be made as follows

Grants in aid (£1000–£3000) will be given to non-profit institutions with basic facilities and qualified personnel for medical research to be used in support of a specific programme *of investigation under the* direction of a particular investigator

Research fellowships in Australia and New Zealand (£2000–£2250) will be granted for one year, but renewal for further periods may be approved

Travelling fellowships (£2250–£2750) will be granted for a period of two years abroad, followed by a third year in an approved institution in Australia or New Zealand

Further information and application forms, which should be returned by July 1, may be had from Dr B C Sinclair-Smith, medical director of the fund, 87 Pitt Street, Sydney, New South Wales, Australia

World Health Day

World Health Day is observed each year on April 7 to mark the anniversary of the coming into force of the constitution of the World Health Organisation in 1948 The theme chosen for 1960 is Malaria Eradication—a World Challenge

Mr Terence Cawthorne is to be the guest of honour at the annual meeting of American Laryngological, Rhinological, and Otological Society in Miami on March 15

The annual general meeting of the Anglo-German Medical Society will be held on Friday, March 18, at 8 P M, at 41, Portland Place, London, W 1

Vitamins Limited have some tickets for watching the Boat Race from their premises on April 2 Applications should be sent to 23, Upper Mall, Hammersmith, London, W 6

Diary of the Week

MARCH 13 TO 19

Sunday, 13th

Institute of Laryngology and Otology, 330, Gray s Inn Road, W C 1
10 15 A M Mr S E Birdsall Problems in Otolaryngology

Monday, 14th

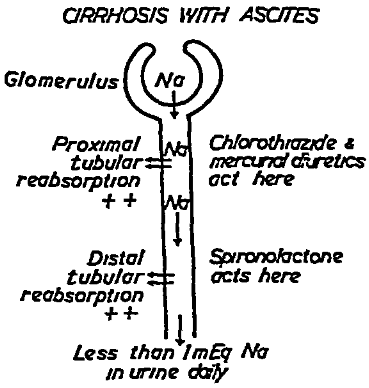
THE DEPARTMENT OF MEDICINE, ROYAL FREE HOSPITAL,
LONDON, W C.1

THE mechanism of renal salt and water retention associated with the formation of ascites in patients with hepatic cirrhosis seems to involve both proximal and distal renal tubules An important feature is the increased production of aldosterone, or the reduced rate of its inactivation by the liver (Peterson 1959, Ulick 1959), which increases sodium retention and potassium loss at the level of the distal renal tubule (Wilde et al 1959) This aspect can be treated by giving aldosterone antagonists, of which the spirolactones are the best available (Cella and Kagawa 1957, Liddle 1958) Although sometimes effective in ascites and cirrhosis, Kerr et al (1958) noted an unsatisfactory diuresis with an intramuscular spirolactone, SC 8109, in three cirrhotic patients with ascites This may be explained by postulating increased proximal tubular reabsorption of sodium and water, so that too little sodium reaches the distal tubule, where the anti-aldosterone action of spirolactones would prevent sodium reabsorption It seemed desirable, therefore, to combine the spirolactones with chlorothiazide, a diuretic which acts primarily on the proximal renal tubular reabsorption of sodium (Vander et al 1959) A double action would thus be produced on the renal tubule. Sodium not reabsorbed in the proximal tubule due to the effect of chlorothiazide would pass to the distal tubule where it would remain unabsorbed due to the aldosterone antagonist, hence it would reach the urine (fig 1)

Mannitol was used as an osmotic diuretic to increase the filtered load of sodium and water reaching the distal tubule, so permitting the aldosterone antagonist to be more effective Mannitol also increases the volume of water excreted in relation to solutes ("free water" clearance) in cirrhosis (Schedl and Bartter 1958)



CIRRHOSIS WITH ASCITES

Spironolactone acts here
Less than 1mEq Na in urine daily

Fig 1—Renal tubular reabsorption of sodium in cirrhosis with ascites.

Avid sodium retention is probably due to increased proximal and distal tubular reabsorption of sodium. Chlorothiazide and mercurial diuretics are thought to inhibit proximal sodium reabsorption whereas spironolactone acts by inhibiting the action of aldosterone on the distal tubule

We have used spironolactone (SC-9420, 'Aldactone'), a thioacetic acid derivative of the steroid-17-spirolactone series, which is the most potent oral aldosterone antagonist available (Gantt and Dyniewicz 1959) We tested the diuretic action of this substance alone and in combination with mannitol and chlorothiazide in cirrhotic patients with resistant ascites

Read et al (1959) found that chlorothiazide, although an effective diuretic, produced hepatic coma in certain patients with liver disease This was attributed to excessive potassium loss associated with alkalosis, and the frequency of hepatic coma was reduced by giving potassium supplements Because spirolactones inhibit urinary potassium loss they might prevent the potassium depletion and consequent hepatic coma We also noted the effect of the drug combination on the neuropsychiatric state of the patients

The Investigation

Patients Studied

Eight patients with portal cirrhosis, and one with biliary cirrhosis, were studied (table I)

TABLE I—PATIENTS STUDIED

Case no	Sex	Age (yr)	Ætiological factor	Duration of ascites (mos)	Previous treatment
1	M	62	Unknown	8	Low-Na diet, chlorothiazide, mersalyl, paracentesis × 10
2	F	44	Primary biliary	8	Low-Na diet, mersalyl
3	F	31	Post-hepatitis	14	Low-Na diet, chlorothiazide, paracentesis × 30
4	M	43	Alcoholism	16	Low-Na diet, chlorothiazide, paracentesis × 6
5	F	72	Unknown	13	Low-Na diet, chlorothiazide, mersalyl paracentesis × 4
6	M	34	Unknown	10	Low-Na diet, chlorothiazide, mersalyl, paracentesis × 5
7	F	38	Post-hepatitis	14	Low-Na diet, chlorothiazide, paracentesis × 3
8	F	17	Post-hepatitis	15	Low-Na diet, chlorothiazide, mersalyl, paracentesis × 3
9	F	56	Unknown	10	Low-Na diet, chlorothiazide, paracentesis × 3

All the patients had tense ascites which had persisted for 8–16 months (mean 12 months), and four had gross peripheral œdema. The ascites had proved refractory to rest in bed, dietary sodium restriction (22 mEq per day), and mercurial diuretics or chlorothiazide. All the patients had required paracentesis several times Their serum-albumin levels were 2 5 g per 100 ml or less All the patients had portal hypertension, shown by splenomegaly, radiological evidence of œsophageal varices, and a raised intrasplenic pressure. Cases 2 and 6 had previously been in hepatic coma.

Methods

The patients received daily 22 mEq sodium, 80 mEq potassium, and 80 g protein (except cases 2 and 6, which received 40 g protein) Fluid intake was measured but not restricted. The patients were weighed daily, and the urinary volume, sodium, potassium, and chloride were estimated 24-hourly The serum sodium, potassium, chloride, and bicarbonate, and arterial ammonium levels (Seligson and Hirahara 1957) were estimated three times a week. Liver function (by routine tests) and blood-urea were estimated weekly Electroencephalograms were analysed, slowing of the mean frequency indicating hepatic precoma (Laidlaw 1959)

Spironolactone 200 mg was given twice daily by mouth, chlorothiazide 0 5 g 6-hourly, and mannitol 200 g. as a 10% solution intravenously over a 6-hour period.

7125

*These patients had a second course of spironolactone, chlorothiazide, and mannitol

During the control period of 5 days the patients had a constant diet The following combinations of diuretics were used (fig 2)

1 Chlorothiazide for 3 days
2 Spironolactone for 3 days
3 Mannitol infusion
4 Spironolactone, with mannitol on the 2nd day
5 Spironolactone and chlorothiazide for 3 days
6 Spironolactone for 3 days, with mannitol on the 2nd day, and chlorothiazide on the 2nd and 3rd days

All the patients had reverted to their pretreatment state as judged by urinary sodium and potassium levels, before a new combination was used

Results

Control period—The basal level of urinary sodium excretion was less than 1 mEq daily except in three patients (cases 1, 2, and 7), urinary potassium levels varied from 25 to 61 mEq per 24 hours, and urine-volumes ranged from 600 to 1100 ml per day (table II, fig 2) Under these conditions the gain in weight was very slight in all the patients except one (case 6) in whom, after a recent paracentesis, ascites was reaccumulating despite sodium restriction None of the patients was at the terminal stage of liver failure (Hecker and Sherlock 1956) when the trial was started They were all very emaciated and had various degrees of abdominal discomfort from the tense ascites

Spironolactone—The mean 24-hour urinary sodium excretion rose in all patients whilst urinary potassium loss was reduced (fig 2) This effect was not noted until 24 hours after spironolactone was started, but it persisted for 48–72 hours after the drug was discontinued (fig 3) In view of this prolonged action, the urinary electrolyte excretions are expressed as a mean of five daily collections In only three patients (cases 1, 2, and 7—i e, those with the higher basal sodium excretions) was the ascites affected clinically, as shown by reduction in weight and increase in urine-volume (table II) Serum-potassium levels rose slightly in all patients Serum-sodium levels were unaltered, except in three patients, where striking natriuresis was associated with reduction in serum-sodium levels (table III)

Mannitol—A 6-hour intravenous infusion of mannitol resulted in an increase of mean urine-volume over 3 days, even allowing for the 2 litres infused Urinary sodium levels were not affected, but potassium excretion rose slightly (fig 2) Creatinine-clearance was unchanged in one patient (case 8) Clinically the patients' condition was unaltered

Spironolactone and mannitol—Addition of mannitol on the 2nd day of the 3-day course of spironolactone produced a dramatic diuresis with loss of weight on six out of nine occasions (table II, fig 3) For the whole group the urinary sodium level increased more than 100% over that achieved with spironolactone alone, while the urinary potassium excretion did not increase significantly (fig 2) In three patients (cases 3, 8, and 9) urinary sodium loss increased tenfold over that produced by spironolactone alone (table II) Serum-potassium levels were unaltered, but serum-sodium levels rose significantly in the six

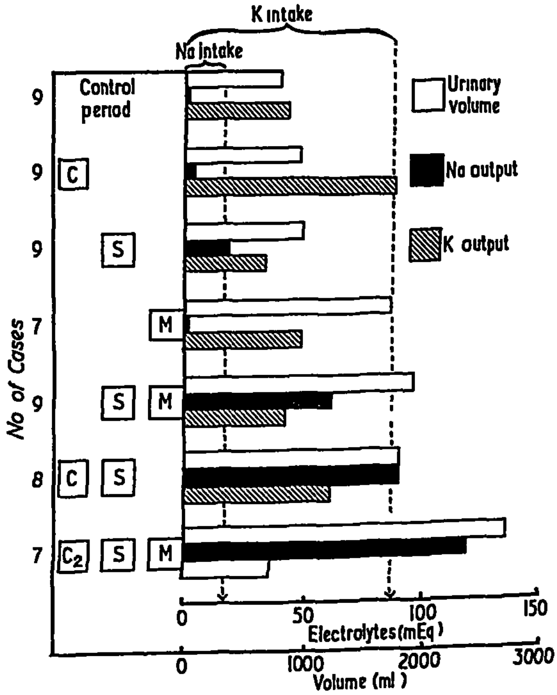

Fig 2—Mean 24-hour urinary volume, and sodium and potassium output in patients with cirrhosis and resistant ascites during treatment with spironolactone (S) 400 mg daily for 3 days, mannitol (M) 2 litres of 10% solution intravenously over 6 hours alone or on the 2nd of a 3-day course, and chlorothiazide (C) 2 g daily for 3 days, or (C₂) 2 g daily on the 2nd and 3rd days of a 3-day course alone and in combination

The means for each patient were derived from a 5-day collection starting with each new combination of drugs, except in the case of mannitol where the means were from a 3-day collection

TABLE III—CHANGES IN SERUM SODIUM AND POTASSIUM LEVELS (IN MEQ PER LITRE) AFTER 3-DAY COURSES OF CHLOROTHIAZIDE AND SPIRONOLACTONE ALONE AND COMBINED WITH MANNITOL

Case no	Control		Chlorothiazide		Spironolactone		Spironolactone and mannitol		Spironolactone and chlorothiazide		Spironolactone, chlorothiazide,* and mannitol

9	133	3·8	−1	−0·7	−1	+0·1	+8	−0·1			+9	+0·3

*Given on 2nd and 3rd days of the 3-day course only

patients in whom a weight-losing diuresis was stimulated (table III) The mean urine-volume increased in these six patients by over 800 ml per day compared with the effect of spironolactone alone, after the increased fluid intake with mannitol was taken into account (table II)

Chlorothiazide—When given at the beginning of the trial, this diuretic produced an increase in potassium excretion (table II, fig 2) with a fall in serum-potassium level, and it did not affect urinary sodium loss (table III) In two patients (cases 2 and 9) this effect was associated with clinical evidence of hepatic precoma, slow waves appearing in the electroencephalogram, and arterial ammonium and pH levels rising

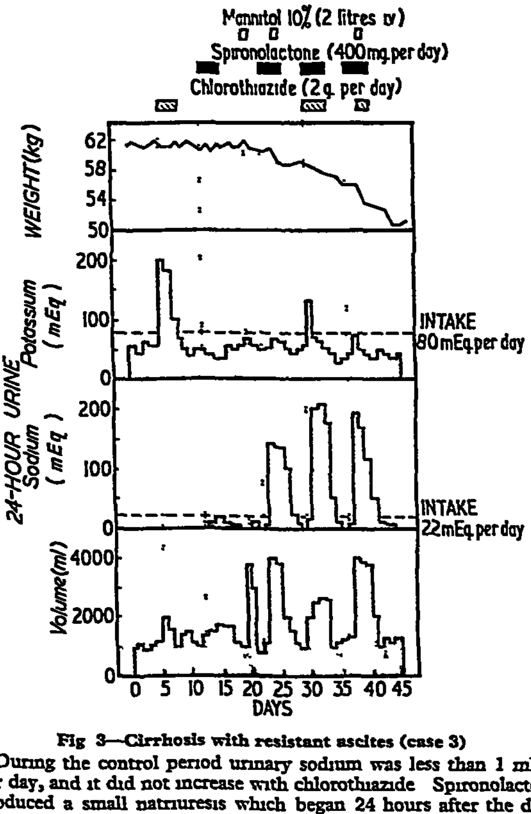

Fig 3—Cirrhosis with resistant ascites (case 3)

During the control period urinary sodium was less than 1 mEq per day, and it did not increase with chlorothiazide Spironolactone produced a small natriuresis which began 24 hours after the drug was started, and persisted for 72 hours after it was stopped The addition of mannitol produced a marked natriuresis with increase in urinary volume and weight loss Chlorothiazide and spironolactone caused a greater loss of sodium than water, and hyponatræmia developed Mannitol corrected the hyponatræmia and increased the water and sodium loss The kaluretic effect of chlorothiazide was corrected by spironolactone after chlorothiazide was omitted on the 1st day of the course

Chlorothiazide and spironolactone produced a considerable natriuresis seven out of eight times (table II), but this was always associated with a tendency to hyponatræmia (table III) Serum-potassium levels fell slightly, being related to the kaluresis the day before the spironolactone was effective (fig 3) In case 2 hepatic precoma again developed and was associated with a sharp fall in serum-sodium as well as a reduction in serum-potassium levels (table III) Most patients felt weak and drowsy at the time of greatest diuresis The loss of sodium in the urine was greater than that achieved with spironolactone and mannitol

Chlorothiazide, spironolactone, and mannitol—On all seven occasions this combination of drugs successfully promoted a diuresis, with consequent weight loss but without hyponatræmia or hypokalæmia (table III) Urine-volumes increased threefold over those of the control period, sodium loss increased but urinary sodium concentrations were not as high as those produced by spironolactone and chlorothiazide, and potassium loss was reduced (fig 2) In all cases weight loss was greater when this combination of drugs was given (table II) Serum-sodium levels rose in all patients Their appetites improved strikingly, and they had a general feeling of well being

General Results

At the conclusion of the trial seven of the nine patients were completely free of ascites for the first time in over a year (table IV) They were up in the ward, and they felt extremely well Their weight loss averaged 11 kg A rise in serum-albumin level, averaging 0·6 g per 100 ml, was associated with a slight increase in hæmatocrit (table IV) The other two patients (cases 5 and 6) were never satisfactorily controlled In case 6 a diuresis was obtained only once, and this was not sustained, he later died following a large hæmorrhage from œsophageal varices

Five of the seven patients who became free of ascites have since remained free from œdema for periods of 8–23 weeks without spironolactone, this has been associated with a fall in hæmatocrit and a further rise in serum-albumin of 0·7 g per 100 ml The other two patients (cases 4 and 8) reaccumulated ascites as outpatients (without spironolactone) and their serum-albumin levels fell

Discussion

The ability of spironolactone to promote sodium loss whilst conserving potassium suggests that the drug acts by inhibiting aldosterone This accords with the observations of Liddle (1958) on the mode of action of an earlier spirolactone SC 8109

The failure to increase urinary sodium loss by the use of chlorothiazide, which acts on the proximal tubule,

suggests that sodium was reabsorbed in the distal tubule, probably under the influence of aldosterone Conversely spironolactone had little effect on the patients who excreted less than 1 mEq of sodium in the urine daily, suggesting that sodium was also reabsorbed proximal to the action of the aldosterone antagonist The synergistic effect on sodium excretion obtained with mannitol, which acts proximally, or with chlorothiazide combined with spironolactone, might be explained by a simultaneous blockade of proximal and distal tubular sites of sodium reabsorption

Hypokalæmia was effectively prevented by omitting chlorothiazide on the 1st day when there was little effect from spironolactone The most effective combination of drugs for achieving natriuresis without hyponatræmia or hypokalæmia was spironolactone, chlorothiazide (for 2 days only), and mannitol

Hyponatræmia tended to appear when spironolactone was combined with chlorothiazide This suggests that relatively more sodium than water was excreted, and accords with the observations of Laragh et al (1958) that chlorothiazide does not increase “ free water ” clearance The combination of spironolactone with chlorothiazide appears to have accentuated the disturbance of water excretion in cirrhosis with ascites One patient (case 2) developed hepatic precoma when given chlorothiazide and spironolactone, although the serum-potassium levels fell only slightly, the serum-sodium level, however, decreased from 135 to 124 mEq per litre Hyponatræmia has also appeared in patients who developed hepatic precoma when taking chlorothiazide (Read et al 1958), and the hepatic coma which follows paracentesis is often associated with hyponatræmia (Nelson et al 1951) A low serum-sodium level in the untreated patient with decompensated cirrhosis suggests a disturbance of water distribution between the intracellular and extracellular spaces, as total body-sodium in these patients is not reduced Possibly diuretics, by producing a disproportionate loss of sodium in excess of water, accentuate this disturbance

Prednisone will correct hyponatræmia in cirrhosis with ascites, promoting at the same time a water diuresis often unassociated with sodium (Stormont et al 1959) Morrison and Chalmers (1959), using prednisone in combination with spironolactone and chlorothiazide, were able to prevent hyponatræmia The mechanism of this action of prednisone is not understood, but it is not related to changes in aldosterone secretion, nor to alterations in glomerular filtration rate or antidiuretic hormone effect Unfortunately fulminant infections often complicate the long-continued use of prednisone in these patients (Stormont et al 1959)

Mannitol can achieve similar results when used with spironolactone and chlorothiazide Osmotic diuretics may be as effective as steroids, and they do not encourage complicating infections The action of mannitol in these patients does not seem to be related to changes in glomerular filtration rate because creatinine-clearance is unchanged It probably reduces proximal tubular reabsorption of sodium and water, this may be greatly increased in cirrhosis with resistant ascites, and is responsible for hyponatræmia and reduced “ free water clearance ” (Schedl and Bartter 1958) The cause of increased proximal tubular reabsorption of sodium and water in such patients is not understood, but Schedl and Bartter (1958) suggest that it is independent of the effect of antidiuretic hormones, and our indirect evidence suggests that aldosterone is not concerned

The beneficial effect of spironolactone in patients with cirrhosis and resistant ascites marks an important landmark in treatment Adjuvant diuretic therapy is clearly essential, for aldosterone is only one factor in the maintenance of ascites The most encouraging results were seen in patients in whom ascites did not reaccumulate when spironolactone therapy was stopped, in these the increase of plasma-volume was associated with a rise in serum-albumin levels It would be extremely interesting to know whether the aldosterone secretion-rate had fallen in these patients, because the increase in their plasma-volumes may have reduced the stimulus to aldosterone production (Bartter et al 1956) Continued freedom from ascites without the need for aldosterone antagonists suggests that hyperaldosteronism is no longer a major problem

Summary

Nine patients with cirrhosis and resistant ascites were treated with an aldosterone antagonist spironolactone, alone and combined with chlorothiazide and mannitol In seven cases ascites was cleared completely

Spironolactone was more effective given in combination with chlorothiazide, but this often caused hyponatræmia The addition of mannitol (an osmotic diuretic)

to the combination corrected the hyponatræmia and increased the natriuresis

Thus resistant ascites may develop in cirrhosis when proximal tubular reabsorption of sodium becomes very high, and mannitol may reduce this tendency whilst increasing the volume of water excreted in relation to solutes (“ free water ” clearance)

We are grateful to Dr R M Haslam for biochemical assistance in the early stages of this work, to Dr John Laidlaw for the electroencephalographic reports, to the Medical Research Council for a grant to J McL , to Dr G R Venning, of Messrs G D Searle & Co , for gifts of spironolactone and help with technical expenses, and to the Dowager Countess Peel research fund

ROLE OF FUNDUS IN PREVENTION OF GASTRO-ŒSOPHAGEAL REGURGITATION

H M GOLDBERG
M.B Lond , F R.C S

CONSULTANT SURGEON, VICTORIA MEMORIAL JEWISH HOSPITAL AND BOOTH HALL HOSPITAL, MANCHESTER

THE mechanism which normally prevents reflux of gastric juice into the œsophagus and which becomes inefficient in the presence of a sliding hiatus hernia has never been satisfactorily demonstrated

Allison (1948) described the pinchcock action of the diaphragm seen during œsophagoscopy It was realised that this played little part in the prevention of regurgitation when it was shown that operations which interfered with the gastro-œsophageal junction, but which left the diaphragm unaltered—such as cardioplasties or œsophago-gastrostomies—were followed by œsophagitis in a high proportion of cases Barium-swallow studies and manometric tracings of pressures in the œsophagus and stomach (Atkinson et al. 1957, Botha et al. 1957, Creamer and Pierce 1957) show a sphincteric function of the lower œsophagus, although no sphincter can be demonstrated anatomically Why this mechanism should fail when the cardia is situated above the diaphragm could not be explained. Widening of the angle of insertion of the œsophagus into the stomach has been held responsible for regurgitation in hiatus hernia (Franklin 1958, Marchand 1955), but careful radiological measurement of this angle failed to support this view (Atkinson et al 1958)

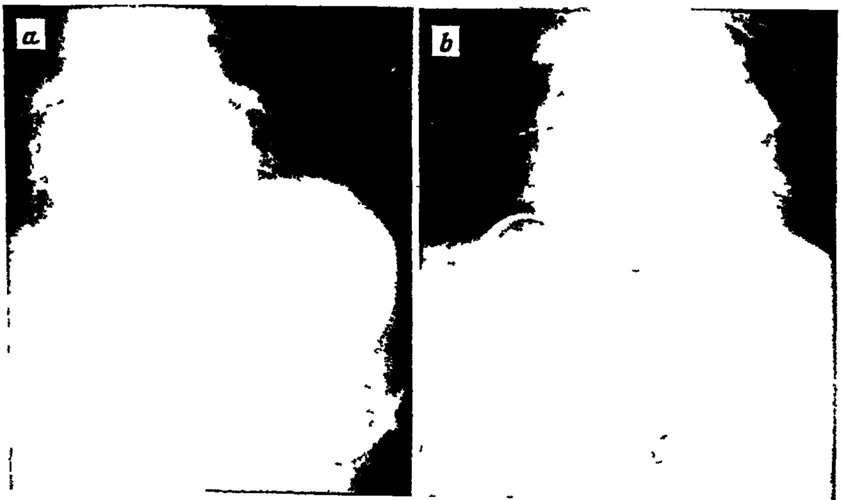

Fig 1—Case of hiatus hernia in a 52-year-old patient *a*, gastro-œsophageal regurgitation after freeing gastro-œsophageal region, *b*, absence of regurgitation after stomach was approximated to œsophagus.

Botha (1959) concluded from his extensive study of the cardiac mechanism that the mucosal folds of the cardia acting in harmony with the “ internal sphincter ” of the lower œsophagus form the closing device between the stomach and œsophagus The even distribution of pressure along the gastric wall in the normal stomach ensures that there is rarely sufficient localised force to overcome the closing mechanism In a sliding hiatus hernia the cardia becomes a funnel, directing the intragastric pressure towards the œsophagus In these circumstances sufficient pressure is more easily built up to give rise to cardiac incompetence

One of the steps employed by many surgeons in the operation for repair of hiatus hernia is suturing of the fundus to the lower œsophagus This step was included in the operation in order to re-establish the gastro-œsophageal angle Although the importance of this angle has been disproved, and Botha (among others) considers this step useless, the impression has been gained that these sutures help to prevent œsophageal regurgitation In order to test the usefulness of these sutures the following experiments were carried out.

Investigation

4 patients with sliding hiatus hernia who had not responded to conservative treatment were submitted to laparotomy through a left upper paramedian incision

After freeing of the lower œsophagus, the fundus, and the edges of the œsophageal hiatus, 10 oz of diluted barium was introduced into the stomach through a stomach-tube The stomach-tube was withdrawn into the œsophagus The abdominal wound was approximated and the patient put into the Trendelenburg position After two minutes an X-ray was taken of the cardiac region, and subsequently the regurgitated barium was aspirated from the œsophagus After levelling the operating-table, a series of sutures was placed between the left border of the œsophagus and the greater curvature of the stomach, restoring as perfectly as possible the normal anatomical appearances of the cardiac and fundal region. Barium was then reintroduced into the stomach, the stomach-tube again withdrawn, the patient put into the Trendelenburg position, and the wound edges approximated After two minutes a further X-ray was taken and the amount of barium in the œsophagus again measured

Fig 1*a* shows the free gastro-œsophageal reflux in a 52-year-old patient after freeing of the gastro-œsophageal

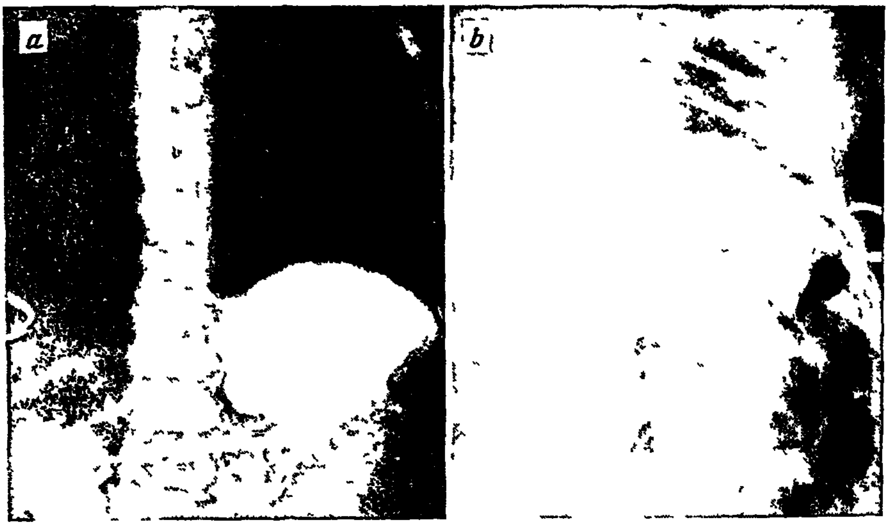

Fig 2—Case of hiatus hernia in an infant *a*, free œsophageal regurgitation before insertion of gastro-œsophageal sutures, *b*, appearance after insertion of sutures

region from the diaphragm Fig 1*b* shows the absence of any regurgitation after a fundus was re-created Fig 2 shows the same appearances in a baby Aspiration records show the difference in the amount of reflux before and after the insertion of the gastro-œsophageal stitches (see table)

ASPIRATION RECORDS

Patient's age	Amount introduced (oz)	First aspiration (oz)	Second aspiration (ml)
56 yr	10	4	0
48 yr	10	3	4
52 yr	10	3½	3
9 mos	4	1	2

The insertion of a series of stitches between the œsophagus and fundus of the stomach was incorporated in 28 operations for repair of a sliding hiatus hernia, and was carried out without repair of the diaphragmatic defect in 2 patients with recurrent hiatus hernia The operations were performed between 1952 and 1957 The patients included in this series were all operated on through an abdominal approach by a technique similar to that described by Tanner (1958) Of the 28 patients with hiatus hernia, 4 had gallstones also, and were submitted to cholecystectomy at the same time as their herniæ were repaired 1 patient had a large hydatid cyst above the right lobe of the liver, this was first discovered during laparotomy and had to be removed at a subsequent operation

Follow-up examination in 1958 showed no residual symptoms from the hiatus hernia in any of the patients 2 patients had unsatisfactory results In 1 pyloric stenosis developed (this condition was probably present at the time of the hiatal repair but was unrecognised) The 2nd patient had an incisional hernia of the laparotomy scar

Discussion

The simple procedure of suturing the fundus of the stomach to the side of the abdominal œsophagus apparently helps to prevent gastro-œsophageal reflux Prior to the first measurement and radiograph in the experiment, the area of the hiatus was cleared and the hernial sac was excised Reflux was still free The fundus was then approximated to the lower œsophagus by two or three sutures Repeat measurements of œsophageal contents and the second radiograph show that this step alone reduces regurgitation to a very small amount This conclusion was confirmed in the 2 cases of secondary repair of hiatus hernia, where these sutures alone were employed

Atkinson et al (1958) showed that the cardiac angle varied considerably in healthy patients as well as in patients with gastro-œsophageal reflux It is impossible to recognise the exact site of the gastro-œsophageal junction, and it is difficult to see how an angle, produced even a few centimetres away from the anatomical junction, could re-establish efficient mucosal folds at the cardia It is therefore not on this angle that the efficiency of these sutures depends

Botha (1959) has pointed out that the intragastric force is spread over a wider area when the anatomy is normal It is the fundus which provides most of the area over which any upward pressure is dissipated It receives most of the gastric contents when intragastric pressure is directed cranially The thin-walled fundal pouch is then distended and both compresses and angulates the lower œsophagus, which is fixed by the branches of the left gastric artery This appearance can readily be seen in routine barium-meal examinations Marchand (1955) showed that the intragastric pressure required to overcome the cardiac barrier when the fundus is clamped off is only a third of that in the intact stomach In a sliding hiatus hernia the fundus disappears early and the cardiac region resembles a funnel, where any backflow easily enters the œsophagus In the rolling type of hiatus hernia, a fundus remains and regurgitation does not take place

Infants regurgitate their feeds with great ease The diaphragm in infants is an almost flat fibromuscular sheet, allowing little room for fundal development If the abdominal part of the œsophagus is short, even less fundus can form and free œsophageal regurgitation can take place, leading to œsophagitis in the absence of a hiatus hernia With growth the diaphragm becomes more arched, with consequent fundal development Free œsophageal regurgitation will therefore cease and the condition of " lax œsophagus " will not be seen beyond the first few months of life 4 infants on whom I operated because of œsophagitis due to a " lax œsophagus " were cured by placing a greater length of œsophagus below the diaphragm

Recurrence after repair of a hiatus hernia has been frequently reported Wells and Johnson's (1955) recurrence-rate was 30% In order to prevent the gastric juice reaching the œsophagus additional procedures have been recommended Tanner usually adds vagotomy to his repair Wells and Johnson do not repair the hernia but abolish peptic activity by gastrectomy and vagotomy Merendino and Dillard (1955) used a method of jejunal interposition Normally a fundus re-establishes itself, even without its being re-formed at operation, when the stomach is placed in its normal position and there is room for a fundus to form This does not happen invariably, and such variability may be responsible for the uncertain results of the usual repair

Summary

An experiment was designed to show the reduction in oesophageal reflux after suturing the fundus of the stomach to the lower end of the oesophagus in cases of hiatus hernia

The presence of a fundus is apparently important in the prevention of reflux

UNIVERSITY COLLEGE, IBADAN

Much information about aminoacid intake can be obtained from a study of the free aminoacids of plasma (Richardson et al 1953) Such information should be useful in kwashiorkor, which is basically caused by the deficiency of dietary protein, but surprisingly little is known about the free aminoacids of plasma and urine in this syndrome

Cheung et al (1955) suggested that there may be an abnormal pattern of excretion of aminoacids in the urine. Hansen, Howe, and Brock (1956) concluded that aminoacids are the chief limiting nutrients of the diet on which kwashiorkor develops Their nitrogen balance studies showed that nitrogen retention was better on a mixture of 18 aminoacids including all the essential aminoacids than on a mixture of the essential aminoacid alone Westall (1958) in a study of protein malnutrition in Mexican children found that the level of aminoacids in the plasma was reduced and that all the aminoacids were not affected equally Senecal (1958) did not find paper chromatography of much value in the study of serum and urine aminoacids in cases of kwashiorkor Schendel et al (1959) observed increased aminoaciduria in infants with kwashiorkor

Here we report on the paper chromatography of the free aminoacids of plasma and urine in 50 untreated cases

The Investigation

The studies were made on 50 new untreated cases of kwashiorkor in children aged 1–4 years seen in the pædiatric clinic of University College Hospital, Ibadan, in the year ended March, 1959 On admission the children were kept on glucose-water with added potassium until next morning, when fasting blood and urine specimens were collected

10 ml of the blood was heparinised and used for aminoacid studies The rest was allowed to clot and the serum was used for estimating serum proteins (total and paper electrophoresis) and for liver-function tests (thymol turbidity and flocculation, bilirubin, alkaline phosphatase, glutamic-oxaloacetic transaminase, glutamic-pyruvic transaminase and isocitric-acid dehydrogenase)

After this initial collection, 41 of the patients were treated with a high-protein milk diet, either as outpatients or inpatients (8 were reinvestigated after discharge) The other 9 were treated by two different regimes The children chosen for this part of the study were not seriously ill and so in no immediate danger 3 of them were fed for four days on a diet high in carbohydrate but low in protein (glucose-water, corn-meal gruel, garri, and vegetable soup, calculated to contain less than 5 g protein per day), at the end of this period further samples were collected and the children then received a high-protein diet The remaining 6 patients were fed for four days on the same basic high-carbohydrate diet with a supplement of 2 0 g *l*-methionine per twenty-four hours after collecting further samples these patients were then treated like the others During their four days on the methionine-supplemented diet 2 of the children had gastro-intestinal hæmorrhage, the cause of which remains unexplained

The healthy controls were 25 children of the same age range They belong to a group of 400 who are being studied in order to establish biochemical normals in Nigerian children

Methods

Total amino-nitrogen —Folin's method (Varley 1958) was used initially on the plasma but a modification of the ninhydrin procedure (Harding 1916) was employed in the last 15 cases to estimate the amino-nitrogen in the desalted ultrafiltrate

Paper chromatography —The equipment and techniques are those described by Smith (1958)

Plasma was deproteinised by ultrafiltration through ultrafiltration shells, and the ultrafiltrate was desalted in an electrolytic desalter The desalted ultrafiltrate was freeze-dried and the residue finally redissolved in distilled water, so that 0 5 ml of the desalted ultrafiltrate was taken up in 25 µl of distilled water 25 µl of the

Solvents butanol/acetic-acid-water, phenol/water/ammonia Papers heated for 2 minutes at 110°C

concentrated ultrafiltrate was applied to each filterpaper square The solvent systems used were butanol/pyridine/water or butanol/acetic-acid/water followed by phenol/water/ammonia

Duplicate sets of papers were usually prepared The ninhydrin colours in one set were developed at room temperature because this produces better contrast as well as a cleaner background for photographs, which were taken three hours after the papers were dipped in ninhydrin solution The colours in the duplicate papers were developed by heating for two minutes at 110°C Besides demonstrating β-aminoisobutyric acid, the heated papers often show substances in low concentration, such as ethanolamine, when they are absent or very faint on the paper developed at room temperature

50 µl of desalted urine was applied to each filterpaper square

Serum bilirubin, thymol turbidity and flocculation, and *alkaline phosphatase* were determined as previously described (Edozien 1958) *Glutamic-oxaloacetic transaminase* and *glutamic-pyruvic transaminase* were measured by the spectrophotometric method (Karmen 1955, Wroblewski and LaDue 1956)

For serum *isocitric-acid dehydrogenase* the method of Wolfson and Williams-Ashman (1957) was chosen but the results have been expressed in spectrophotometric units at 25°C as proposed by Baron (1958, 1959a, b)

Results

Mean values for fasting plasma aminoacid nitrogen in healthy children are 5 2 mg per 100 ml (4 1–8 0 mg) by the method of Folin and 4 3 mg per 100 ml (3 5–6 1 mg) by the ninhydrin procedure The corresponding mean values in the kwashiorkor patients are 2 5 mg (2 0–4 5 mg) and 2 1 mg (1 3–3 5 mg) In kwashiorkor, therefore, plasma level of amino-nitrogen is about 45% of normal

The plasma free-aminoacid pattern in the healthy Nigerian children (fig 1a) does not differ in any significant respect from that described for European children and adults (Smith 1958) In kwashiorkor the plasma amino-acid chromatograms showed a general decrease in the intensity of the ninhydrin-reacting spots This loss of intensity, however, is not uniform

The following amino-acids seem to be most affected (fig 1b, c) cystine (shown as cysteic acid on samples treated with hydrogen peroxide before being spotted), methionine plus valine plus tryptophan as one spot, leucine plus isoleucine plus phenylalanine as one spot, threonine, and arginine Because most of these aminoacids are located at the top left-hand corner of the square, in many cases the spots in this region of the chromatogram are hardly visible while the spots in other parts of the chromatogram stand out quite distinctly It is of considerable interest that all these amino-acids are essential aminoacids It is also to be noted that lysine did not often behave like the other essential aminoacids

Ethanolamine could not be detected in any of the normal chromatograms but was clearly visible in about 75% of the cases of kwashiorkor β-aminoisobutyric acid also could not be located in any of the control plasmas but was found in 30% of the cases of kwashiorkor

The pattern of aminoacid excretion in the control children was not different in any significant respect from the pattern found in healthy European children (fig 2a) Ethanolamine was absent from all the control urines, and β-aminoisobutyric acid could be identified in only 8% this result is in striking contrast to the experience of Lindan (1952) who found this aminoacid in 45% of healthy Gambian Africans

The kwashiorkor urines showed a variable amount of aminoaciduria judging by the number and intensity of the ninhydrin spots (fig 2b)

The non-essential aminoacids were chiefly affected; only rarely could essential aminoacids be identified on the chromatograms. Ethanolamine was excreted in 80% of the cases. β-aminoisobutyric acid was identified in every case; indeed in many of the pathological urines it was the dominant aminoacid spot.

The experimental feeding with the high-carbohydrate low-protein diet alone did not noticeably alter the urine chromatograms but there was a distinct reduction in the intensity of the spots in the plasma chromatograms.

The methionine-supplemented diet produced a marked increase in all the plasma aminoacids, including the essential aminoacids. In the 3 cases of this group in which ethanolamine was initially identifiable in the plasma, it disappeared after the administration of methionine. In the urine the excretion of ethanolamine was greatly diminished in all 6 cases (fig. 3); in 3, indeed, it could no longer be identified. The excretion of β-aminoisobutyric acid was unaffected by the methionine (fig. 3). These results are summarised in table I.

Plasma and urine aminoacid chromatograms of the clinically cured patients who were re-examined appeared normal.

Table II gives the mean values for total serum proteins with the protein fractions, and the results of the liver-function tests both in the cases of kwashiorkor and in the controls.

Discussion

Our results with paper chromatography confirm Westall's finding that in kwashiorkor the plasma aminoacids are reduced and that individual aminoacids are affected in different degree. In protein malnutrition there is a qualitative as well as a quantitative deficiency of aminoacids.

The interpretation of the urine chromatograms presents considerable difficulties.

In healthy children and adults comparative urine-aminoacid chromatograms can be produced by applying a timed collection of urine (say 2 seconds urine) or by relating the amount of urine applied to nitrogen content (usually an aliquot containing 625 μg nitrogen), specific gravity, body-weight, or urinary creatinine output. But in making comparisons between kwashiorkor patients and normal children none of these criteria is satisfactory. The pathological urines are of very low nitrogen content; hence, if aliquots containing 625 μg of nitrogen are applied, the volumes used constitute much higher proportions of the daily output than is the case with normal urines, and the amino-nitrogen content of these amounts of urine is so high that resolution is impossible. Moreover, most of the pathological urines were of very low specific gravity, and calculations of quantities based on specific gravity also result in application of large volumes of urine. Relating the quantity of urine to body-weight is unsatisfactory because of the œdema. Creatinine excretion is very variable in kwashiorkor because of the muscle breakdown and the decrease in muscle mass which are features of the disease. These and related matters are discussed by Schendel et al. (1959).

Since the technique of paper chromatography is at best only semiquantitative, we do not consider that our method justified any elaborate adjustment of volumes, which in any case appear to be of doubtful value. We have therefore employed the same volume (50 μl.) of early-morning urine in the study of our normal and pathological urines. In 12 kwashiorkor cases (24%) the concentration of aminoacids in the urine was too high for good separation to be obtained, and in these the chromatography had to be repeated with smaller urine volumes.

TABLE II—LIVER-FUNCTION TESTS IN HEALTHY CHILDREN AND IN KWASHIORKOR

Test	Healthy children (1–4 years)	Kwashiorkor (1–4 years)
Total serum proteins	6·9 g per 100 ml.	4·1 g per 100 ml
Albumin	3·2 ,, ,,	1·3 ,, ,,
α_1-globulin	0·3 ,, ,,	0·3 ,, ,,
α_2-globulin	0·8 ,, ,,	0·5 ,, ,,
β-globulin	0·9 ,, ,,	0·4 ,, ,,
γ-globulin	1·7 ,, ,,	1·6 ,, ,,
Total bilirubin	0·5 (*0·2–0·9*) mg per 100 ml.	0·8 (*0·2–1·8*) mg per 100 ml.
Thymol test (% having turbidity > 4 Maclagan units and flocculation > 1+	0	26
Alkaline phosphatase	27·4 (*17–35*) K.A units	16·7 (*8–36*) K.A units
Glutamic-oxaloacetic transaminase	21·9 (*14·0–30·1*) units per ml	70·5 (*13·6–467·5*) units per ml.
Glutamic-pyruvic transaminase	10·6 (*5·4–17·4*) ,, ,,	31·5 (*10·6–110·0*) ,, ,,
Isocitric-dehydrogenase	11·3 (*3·3–26·1*) ,, ,,	28·7 (*5–181·0*) ,, ,,

Our results are in agreement with the report of Schendel et al that there is increased excretion of aminoacids in kwashiokor We are strengthened in this conclusion by the fact that, had an attempt been made to relate the volumes of pathological urines applied to their specific gravity, nitrogen content, or creatinine content, we should have applied much larger quantities than we did, with consequent increase in the intensity of the aminoacid spots

The aminoaciduria in kwashiorkor must be of the renal type, since the increased excretion occurs in spite of the level of aminoacids in the plasma being reduced Although urine analyses rarely show any urine abnormalities and no specific lesions in the kidneys have yet been described, it still is possible that the renal tubule cells are affected by the generalised loss of cell substance, with consequent decrease in cell proteins including cell enzymes Individual tubular functions depending on enzyme action may therefore suffer Recently it has been shown, for instance, that there is an acidification defect in kwashiorkor (Smith 1959) The aminoaciduria could be the result of changes in the enzyme mechanisms responsible for the tubular reabsorption of aminoacids from glomerular filtrate

It has also been suggested that there may exist in the kidneys a homœostatic mechanism for maintaining the balance of aminoacids in plasma If this is so, the aminoaciduria in kwashiorkor may be an expression of the imbalance of the plasma aminoacids

β-aminoisobutyric acid was first identified in human urine in 1951 (Crumpler et al 1951, Fink et al 1951), and under ordinary conditions its concentration in the urine appears to be genetically controlled (Crumpler et al 1951, Harries 1953) Its excretion is increased, however, in various pathological conditions (Walshe 1953, Pare and Sandler 1954, Sandler and Pare 1954) Feeding experiments in the rat (Fink et al 1952) and in man (Awapara and Schullenberger 1957, Gartler 1959) have pointed to thymine as the probable procursor of this aminoacid

While the high excretion of β-aminoisobutyric acid in kwashiorkor may be partly the result of increased renal clearance, it is out of all proportion to the increased output of the other aminoacids Moreover, in a significant proportion of cases (30%) a rise in the level of this aminoacid in the plasma was large enough to be identified by our technique These findings suggest that it is produced in abnormal quantities in kwashiorkor Such an excess could be derived from cell deoxyribonucleic acid released by the considerable tissue loss in skeletal muscle and other organs Moreover, the possibility must be borne in mind that, as a result of the decrease in the protein and aminoacid pool, there may be a general increase in the turnover-rate of cells This could account not only for an increase in the breakdown of deoxyribonucleic acid but also for the rise in serum glutamic-oxaloacetic transaminase, glutamic-pyruvic transaminase, and isocitric-acid dehydrogenase in cases where there is no other evidence of impaired hepatic function

An alternative explanation, which would account more satisfactorily for the very considerable increase in the excretion of β-aminoisobutyric acid is that the metabolism of this aminoacid is blocked by deficiency of an essential metabolite or disturbance of an enzyme mechanism, but so little is known about the intermediary metabolism of this substance that there is at present no evidence for this hypothesis

For some years it has been recognised that ethanolamine is excreted, along with other aminoacids, in liver disease (Dent and Walshe 1951, Walshe 1953) We suspected that the ethanolaminuria in kwashiorkor may be a very sensitive indication of nutritional liver damage, but we could find no constant relation between the plasma-ethanolamine and ethanolaminuria on the one hand and the liver-function tests on the other Thus about 75% of our cases had a raised level of ethanolamine in the plasma, and 80% had ethanolaminuria, but only 35% had serum-bilirubin levels higher than 1 0 mg per 100 ml, 26% showed abnormal protein flocculation reactions, and only 2% had alkaline-phosphatase levels higher than 35 K A units (the upper limit for the control children) The mean values for glutamic-oxaloacetic transaminase, glutamic-pyruvic transaminase, and isocitric dehydrogenase were higher in the kwashiorkor children than in the control group but no correlation could be established between the enzyme levels and the ethanolaminuria

Table I shows that, except in 1 patient (B 1), administration of methionine did not unequivocally improve liver function, though it always abolished or greatly reduced the ethanolaminuria We conclude, therefore, that the overproduction and overexcretion of ethanolamine is the result not of liver damage but of a metabolic block in the utilisation of this amine for the synthesis of choline. This block results from a deficiency of methyl donors which in our feeding test was corrected with methionine

Summary

The free aminoacids of plasma and urine in kwashiorkor have been studied by paper chromatography

In kwashiorkor the total aminoacid nitrogen of the serum is reduced to approximately 45% of normal value the individual aminoacids are affected in varying degrees

There is an aminoaciduria of renal origin

Excretion of ethanolamine and of β-aminoisobutyric acid is increased Evidence is given which suggests that the ethanolaminuria is due to a metabolic block in the utilisation of ethanolamine The excess β-aminoisobutyric acid could be derived from a similar block in its utilisation, or alternatively from deoxyribonucleic acid released by tissue breakdown and from a general increase in cell turnover rate

Our thanks are due to Dr O Ransoke-Kuti for taking clinical charge of some of the patients on the experimental diets, and to Mrs E Odim and Mr J M Pescod, F I M L.T, for technical assistance

THE MEDICAL UNIT, THE ROYAL INFIRMARY, CARDIFF, WALES

Over two hundred years ago Cadwalader in Philadelphia described a patient whose bones were soft, in part dissolved, and full of large holes, like a honeycomb Four years before her death at the age of 40, she had been "seized with a Diabetes, and the usual symptoms, *viz* a frequent and copious Discharge by Urine, a gradual Wasting of the Body, a Hectic Fever, with a quick, low Pulse, Thirst, great Pains in her Shoulders, Back and Limbs, and Loss of Appetite" (Bevan 1743, Cadwalader 1745)

This was really the first description of hyperparathyroidism, but the clinical features were not clearly recognised until about thirty years ago Since then many have noted polyuria to be a symptom of the disorder, though it is seldom as prominent as in Cadwalader's patient When it is, it may lead to a mistaken diagnosis of pituitary diabetes insipidus The polyuria of hyperparathyroidism does not, however, respond to vasopressin —because the defect is in the renal reabsorption of water and not in the secretion of antidiuretic hormone (Cohen et al 1957) This defect has been attributed to the hypercalcæmia, since it may be encountered with hypercalcæmia from other causes (Epstein et al 1958)

There is some evidence that parathyroid hormone itself may directly impair the tubular reabsorption of water (Epstein et al 1959)

Ellsworth and Nicholson (1935) and Robbins (1937) noted that parathyroid extract injected intravenously in man increased the excretion of water and of sodium. These observations have been confirmed by Nordin (1959) Epstein et al (1959) recently showed that parathyroid extract injected intravenously in dogs diminished the maximum concentration of solutes in the urine during dehydration and impaired the reabsorption of water during an osmotic diuresis produced with mannitol. Moreover, during the osmotic diuresis the dogs' urine was often hypotonic despite the fact that they were infused with vasopressin at the same time as mannitol.

A defect in the tubular reabsorption of water is unlikely without other defects of tubular function Indeed, Ellsworth and Nicholson (1935) found that parathyroid extract decreased the excretion of hydrogen ion in their dogs The excretion of hydrogen ion has not been systematically investigated in hyperparathyroidism in man, but an impaired excretion of hydrogen ion and a systemic acidosis has occasionally been noted with hyperparathyroidism as well as with hypercalcæmia from other causes (Cohen et al 1957, Fanconi and Rose 1958, Wrong and Davies 1959)

We have studied the tubular functions of water reabsorption and hydrogen-ion excretion in patients with hyperparathyroidism who did not have polyuria.

Procedure

Patients

We studied 6 patients with hyperparathyroidism, 4 of them had kidney stones and 2 had not We also studied 3 patients without hyperparathyroidism 2 of them had stones Table I shows the principal clinical findings in the patients with hyperparathyroidism

Of the 2 patients without stones, one was a man with multiple tumours of the parathyroids and of the islets of Langerhans whose original symptoms were the result of hypoglycæmia He showed no radiological signs of bone disease The other was a woman with a solitary osteoclastoma of the lower end of the right femur but no other evidence of bone disease

All the patients with hyperparathyroidism had their parathyroid adenomas removed. 4 of them were studied a second time about a week after the operation, and 2 of them a third time two months after the operation

Tubular Reabsorption of Water

Response to dehydration—The maximum osmolar concentration of the urine (Crawford and Nicosia 1952) was measured after the patient had been deprived of water for between eighteen and twenty-two hours (In the patient with hyperinsulinism we failed to carry out this test satisfactorily)

Response to vasopressin during osmotic diuresis—The reabsorption of water by the renal tubules was measured during an osmotic diuresis produced by infusion of a 25% solution of mannitol

Although it is customary to carry out this test in patients deprived of water, our patients had enough water to make the urine hypotonic before the infusion, and during the infusion we encouraged them to drink. We thought that hydration might reveal defects in the tubular response to vasopressin which might not be apparent in the presence of dehydration (Miles et al. 1954)

An initial dose of vasopressin ('Pitressin' 100 milli-units) was given intravenously as soon as the urine became hypotonic, and throughout the experiment vasopressin was infused at the rate of 5 milli-units per min This rate is more than enough to ensure a maximal response The mannitol infusion was started one hour after the first dose of vasopressin and continued for at least one hour at a rate of about 5–9 ml per min , during this period at least three accurately timed collections of urine were made.

Excretion of Hydrogen Ion

The pH, titratable acidity and ammonia were measured in specimens of urine collected hourly following the

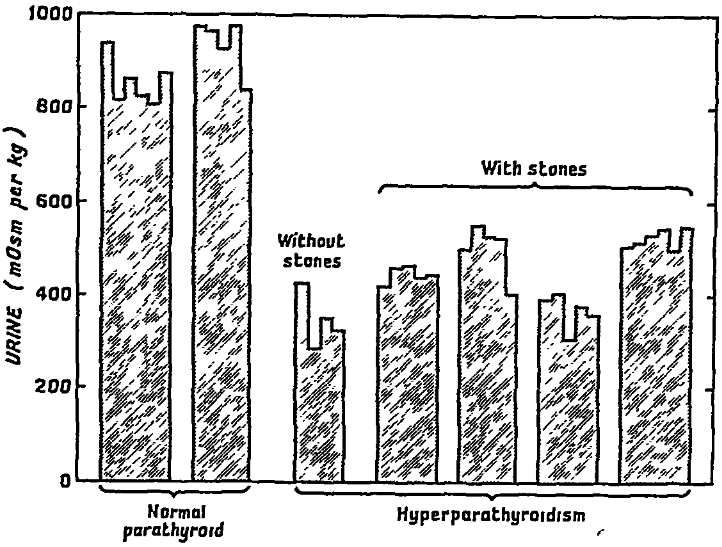

Fig 1—Concentration of urine after deprivation of fluid for 18–22 hours

ingestion of ammonium chloride, 0·1 g per kg body-weight

In carrying out this test in 10 people without renal disease Wrong and Davies (1959) found that the pH of hourly collections of urine fell to a mean value of 4·6–5·2 from the second to the eighth hour after the ingestion of ammonium chloride, the titratable acidity rose to a mean value of 24–51 µEq per min. and the NH_4 to a mean value of 33–75 µEq per min.

Results

Glomerular Function

Glomerular filtration, measured by the endogenous creatinine clearance, was not much impaired (table I) The lowest value encountered was 47 ml per min. in patient G, her blood-urea was 52 mg per 100 ml

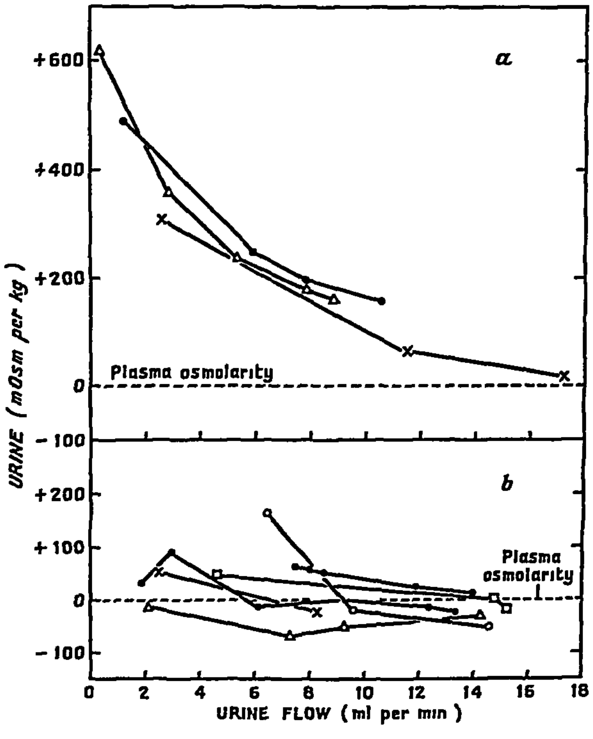

Fig 2—Concentration of urine at increasing rates of flow during an osmotic diuresis (a) in patients without a parathyroid adenoma, (b) in patients with a parathyroid adenoma

Tubular Reabsorption of Water

Fig 1 shows the effect of water deprivation on the concentration of solutes in the urine The maximum osmolality of the urine in patients with hyperparathyroidism ranged from 405 to 550 m Osm per litre, whereas the normal values certainly exceed 700 m Osm and are often greater than 1000 m Osm per litre (Miles et al 1954, West et al 1955) The normal response to a hypertonic infusion of mannitol with pitressin (Wesson and Anslow 1948, Zak et al 1954, Barlow and de Wardener 1959) is illustrated by the results in table II, from the 2 patients with stones who did not have hyperparathyroidism As the rate of excretion of solute increased, the flow of urine increased and its concentration fell, but at all rates of excretion of solute the urine remained more concentrated than the plasma (fig 2a) By contrast, in 4 of the 6 patients with hyperparathyroidism the urine became more dilute than the plasma (fig 2b)

The renal tubules concentrate the urine by reabsorbing water in excess of solute This process takes place in the distal and collecting tubules, under the influence of antidiuretic hormone, fluid which is hypotonic on entering the distal tubules is hypertonic when it leaves the collecting tubules

As the exact concentration of the hypotonic fluid entering the distal tubules cannot be known, the total volume of water reabsorbed in excess of solute cannot be calculated One can, however, calculate the amount of water which has to be reabsorbed to bring the tubular fluid from a concentration isotonic with plasma to its final concentration This amount is denoted by the symbol T^cH_2O (the superscript c standing for "concentrating") and is expressed as "free water"—i e, water reabsorbed independently of solute

$$T^cH_2O = \frac{U_{osm} \times V}{P_{osm}} - V$$

where U_{osm} and P_{osm} are the total solute concentrations, in milliosmoles, in the urine and the plasma, and V is the volume of urine per min. The maximum value of T^cH_2O in normal subjects, 5–7 ml per min, is reached when the urine flow exceeds 7 ml per min. during an osmotic diuresis (Zak et al

* The collections of urine in these two periods may have been inaccurate.

1954, Berliner et al 1958, Barlow and de Wardener 1959) If the final urine is hypotonic T^cH_2O is a negative value

Table III shows the values for T^cH_2O at the height of the mannitol diuresis The 2 young patients without hyperparathyroidism achieved normal rates of free water reabsorption although they both had renal stones The 3rd was much older, and this may be the reason for his relatively poor response

The patients with hyperparathyroidism had abnormally low values, they were negative when the patients were excreting urine hypotonic to their plasma

Excretion of Hydrogen Ion

After the administration of ammonium chloride, the excretion of hydrogen ion was normal in the patients without hyperparathyroidism, even if they had renal stones, it was also normal in those patients with hyperparathyroidism who did not have stones In the patients with hyperparathyroidism and stones, however, this function was defective fig 3 shows that the average pH of the urine remained about 6 in most cases and never fell below 5·4 The excretion of ammonium was smaller than normal It bore the normal relation to the pH of the urine (Wrong and Davies 1959) Because the excretion of ammonium was small, the total excretion of hydrogen ion, measured as the sum of the excretion of NH_4^+ and titrable acidity, was less than normal (fig 4)

In the 4 patients studied one week after their parathyroid adenomas were removed there was little evidence of any improvement In 2 patients studied again after two months both functions had improved, in another patient they had not improved

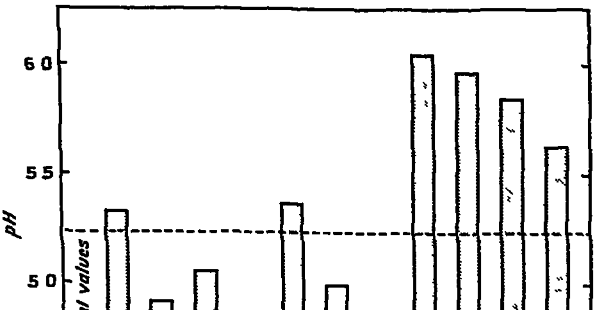

Fig 3—pH of urine after ingestion of ammonium chloride

Discussion

It has long been known that one of the commonest and most serious effects of hyperparathyroidism is renal damage leading to uræmia and death This is the result of renal calcification, stone formation, and infection, and is associated with a severe loss of glomerular function

Another effect of hyperparathyroidism upon the kidneys is damage to the tubules, which may produce the syndrome of renal diabetes insipidus When the syndrome is produced in this way it is the result of a high concentration either of calcium or of parathyroid hormone in the body fluids, as is evident from its rapid correction by removal of the abnormal parathyroid tissue (Cohen et al 1957, Epstein et al 1958) This syndrome is rare

Hyperparathyroidism has a third effect upon the kidneys, which is easily overlooked because it does not cause symptoms Some years ago Hellstrom (1954) noted that, when they were deprived of water, almost all patients with hyperparathyroidism failed to form urine of normal concentration, although their glomerular filtration-rate and the level of urea in their blood might be quite normal This suggested that they all had some tubular damage which interfered with their ability to reabsorb water and to produce a concentrated urine (Edwall 1958) Hellstrom measured the specific gravity of the urine, which gives only a rough idea of the total concentration of solutes

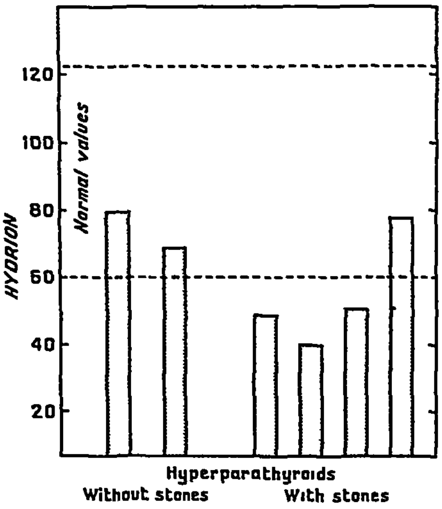

Fig 4—Excretion of H-ion after ingestion of ammonium chloride.

Measuring the concentration of the urine by its osmolality, we have confirmed Hellstrom's findings In addition, we found that, whereas at ordinary rates of solute excretion our patients could produce urine more concentrated than plasma, when they were subjected to an osmotic diuresis the osmolality of their urine fell below that of the plasma although they were having vasopressin. These results show that water reabsorption was depressed They suggest that, when the rate of flow of fluid through the tubules was increased by an osmotic diuresis, enough water could not be reabsorbed to render isotonic the hypotonic fluid delivered to the distal tubules (de Wardener and del Greco 1955) This abnormality is not generally encountered in renal failure, such as may be produced by nephritis, except perhaps when the glomerular filtration is very much diminished and the volume of the urine represents a large proportion of the glomerular filtrate (Baldwin et al 1955)

This defect differs in at least two respects from that previously described in patients with hyperparathyroidism and the syndrome of diabetes insipidus Firstly, it is much less severe, and the concentration of the urine is not necessarily *below* that of the plasma Secondly, there is little recovery immediately after operation, whereas patients with the syndrome of renal diabetes insipidus lose their hyposthenuria and are able to produce at least an isotonic urine quite soon after the removal of a parathyroid adenoma

Persistent hyposthenuria in hyperparathyroidism, with the syndrome of diabetes insipidus, has been attributed to hypercalcæmia The less obvious disturbance of water reabsorption demonstrated in our patients, however, cannot be the result solely of raised levels of calcium or of parathyroid hormone in the body fluids, since these levels fall a few hours after the removal of a parathyroid adenoma Morphological changes produced in the kidney by the parathyroid hormone could be responsible for the functional defects The tubular fluid is concentrated in the distal and collecting tubules, and in hyperparathyroidism calcium is deposited round these segments of the tubules The deposits of calcium can persist for some time after the removal of a parathyroid adenoma (Cohen et al 1957, Epstein et al 1959, Jaccottet 1959)

Hydrogen-ion Excretion and Renal Stone

Impaired reabsorption of water is often associated with a defect in the secretion of hydrogen ion which also takes place in the distal tubule This is the case, for instance, in the Fanconi syndrome and in the syndrome of renal acidosis (Jackson and Linder 1953, Stanbury 1958) Among our patients this association was found only in those whose hyperparathyroidism was complicated by renal stones Infection of the urine may have contributed to the abnormal finding, we do not think this is likely but the point is to be investigated further The patients with stones not due to hyperparathyroidism excreted acid normally It is therefore interesting to consider the bearing of an inability to acidify the urine upon the formation of renal stones

In patients *without* hyperparathyroidism stone formation often begins in the pelvis of the kidney with the extrusion of a plaque of calcium from the tip of a renal papilla (Randall 1940) On the other hand, in patients *with* hyperparathyroidism the stone probably originates in the renal tubules as a cast containing calcium phosphate Although the precipitation of calcium in the renal tubules has naturally been assumed to be the result of a high concentration of calcium in the urine, the finding of more and more patients with hyperparathyroidism and renal stones whose output of calcium in the urine is normal makes this assumption unsatisfactory In our patients the excretion of calcium was usually not large

Thus in patient I it was only 60–200 mg daily, her small excretion of calcium could not be attributed to renal failure, for her creatinine clearance was 79 ml per min., and her blood-urea 30 mg per 100 ml She had bilateral staghorn calculi, and a biopsy of her left kidney, taken when she had a stone removed a month before her operation for a parathyroid adenoma, revealed deposits of calcium around the tubules

Infection might have played a part in the renal calcification, but one would expect this to lead only to the formation of stones in the pelvis Since her excretion of calcium was small it may be suggested that the deposition of calcium in the tubules was facilitated by the relatively alkaline reaction of her urine produced by the defect in hydrogen-ion excretion

We have already suggested that this defect in tubular function might be the result of the initial damage to the tubules produced by the deposition of calcium *around* them, but it is impossible to escape the conclusion that the defect in hydrogen-ion excretion would in turn favour the further deposition of calcium *within* the tubules

Apart from its theoretical interest, the difference in the ability of these two groups of patients with renal stones to excrete hydrogen ion, would (if confirmed) be of practical value in distinguishing between them At present a diagnosis of hyperparathyroidism in patients with stones is often largely based on very small changes in the plasma-calcium level, if a simple test of tubular function were to make this diagnosis easier it would represent a great gain The change in the pH of the urine produced by a dose of ammonium chloride can be measured very easily and the patient does not even have to come into hospital for this to be done It should not, therefore, be difficult to test the suggestion that, among patients with renal stones, those with hyperparathyroidism fail to excrete hydrogen ion normally

Summary

The renal tubular functions of water reabsorption and hydrogen-ion excretion were tested in 6 patients with, and 3 patients without, hyperparathyroidism 4 of the patients with hyperparathyroidism, and 2 of those without, had renal stones

The reabsorption of water was measured by the osmolality of the urine after water deprivation and by the response to an intravenous infusion of hypertonic mannitol given with vasopressin These tests demonstrated that the patients with hyperparathyroidism did not reabsorb water normally

The excretion of hydrogen ion was measured by the changes in pH and excretion of ammonium and titratable acid after the ingestion of ammonium chloride The 4 patients with hyperparathyroidism and stones did not have a normal fall in the urinary pH, their excretion of ammonium and titratable acid was only slightly diminished These functions were normal in all the other patients tested The diminished excretion of hydrogen ion after the ingestion of ammonium chloride in patients with stones due to hyperparathyroidism might therefore have diagnostic value This suggestion could easily be tested in a clinic devoted to renal stones Furthermore there is a possibility that a diminished excretion of hydrogen ion with a relatively alkaline urine plays a part in the formation of renal stone in hyperparathyroidism

The failure to reabsorb water normally, and the impaired excretion of hydrogen ion did not immediately disappear after the removal of a parathyroid adenoma. They are not therefore simply the result of high concentrations of circulating calcium or of parathyroid hormone. They may be the result of a renal deposition of calcium

We are indebted to Prof Harold Scarborough for his encouragement and advice, to Miss P M Leeson for her collaboration at various stages of the work, to Mrs Margaret Lewis, Miss Margaret Hopkins, and Mrs Elgar Cotsen for technical assistance, and to Mr Ralph Marshall for photographs

THE LONDON HOSPITAL, LONDON, E.1

SINCE the recognition of hypertrophic pulmonary osteoarthropathy (H P O.A.) by von Bamberger (1889) and Marie (1890) independently, many and diverse underlying conditions—involving lungs, pleura, mediastinum, and diaphragm—have been found In present-day clinical experience, tumours, and notably bronchial carcinomas, cause H P O A far more often than other well recognised conditions such as pulmonary sepsis

H P O.A. has been described in association with many intrathoracic neoplasms other than bronchial carcinoma Malignant tumours include fibrosarcoma of the lung (Massachusetts General Hospital case no 31271 [Mallory et al 1945]), thymic carcinoma (Miller 1939), and endobronchial plasmacytoma (Plenk and Pretl 1953), benign tumours include localised pleural fibroma (Price Thomas and Drew 1953), neurilemmoma (Trivedi 1958), and neurofibroma (Keller and Callender 1930) Even " pseudotumours " in the thorax, such as aortic aneurysm (Lang and Bower 1930) or gross dilatation of the œsophagus following achalasia or carcinoma (Peyman 1959), seem occasionally to be associated with H P O.A. In contrast to the fairly common phenomenon of H P O.A. complicating primary intrathoracic neoplasms, its association with hæmatogenous metastases from a non-pulmonary primary source is rare

We have recently seen a patient who had had a leiomyosarcoma of the uterus removed successfully 4 years later acute H P O.A developed and was apparently related to " cannon-ball " metastases in the lungs

Case-report

A woman of 49 was referred to the London Hospital in April, 1954 For several weeks she had had anorexia, morning nausea, feverishness, and a dragging lower abdominal pain, and she had gradually become weaker

She was well nourished but febrile Abdominal examination revealed a mass arising from the pelvis and extending towards the left iliac fossa. Her fingers were not clubbed. Before operation she had intermittent fever which did not respond to antibiotics

At laparotomy (Mr Victor Lack) the uterus was found to contain two large tumours, and a radical hysterectomy was done The larger mass was 11 cm. in diameter, with a necrotic centre, histologically it proved to be a leiomyosarcoma, showing numerous giant and atypical cells

The patient's sense of well-being rapidly returned, and her temperature became normal on the day after operation. During the next 4 years she was in good health, and even took a reducing diet because of excessive weight gain In April, 1958, she began to get aching pain over the shins and ankles, particularly towards the end of the day, this slowly increased in intensity and duration. She was readmitted to the London Hospital in July with unremitting pain over the shins and ankles, and to a lesser extent at the wrists

The patient's state of nutrition had remained good. The most striking abnormalities were clubbing of fingers and toes, œdema of ankles, and warm dusky areas overlying the anterior tibial surfaces Her shins were so exquisitely tender that she could not tolerate the weight of bedclothes on her legs Both ankles and wrists were a little swollen and tender The clubbed fingertips were warm but not tender

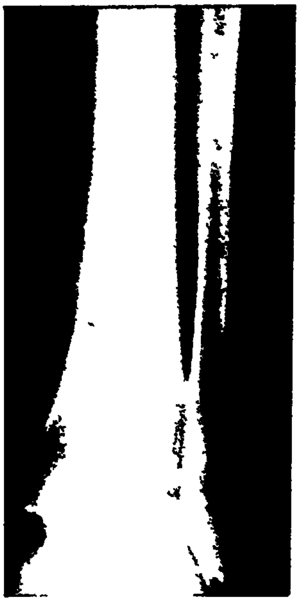

Fig 1—Subperiosteal bone deposition at lower ends of left tibia and fibula.

H.P O.A. was diagnosed This was amply confirmed by the radiological appearance of the shafts of the tibiæ and fibulæ which, in each leg, showed deposition of periosteal new bone (fig 1) Chest radiographs revealed several discrete rounded opacities in both lung fields consistent with blood-borne pulmonary metastases

Apart from radiographical evidence of dissemination to the lungs, there was no clear indication of tumour spread to other parts of the body, nor did examination of the pelvis suggest local recurrence of the leiomyosarcoma. Clearly the relief of the bone pain was a pressing need. Calcium aspirin in daily dosage of gr 100 proved ineffective Vagotomy was considered but it was not thought justifiable to submit the patient to thoracotomy Steroids seemed worth a trial, and prednisone was given, 60 mg daily at first, being reduced after a week to 15 mg As well as general subjective improvement, the local leg pain lessened impressively within 2 days When discharged from hospital on Aug 15 she was able to pursue her normal activities at home She continued to take prednisone 5 mg t.d.s

For many months there was little change in her condition clinically, though serial X-rays showed a gradual increase in the size of the pulmonary deposits (fig 2), and further periosteal new-bone formation But by February, 1959, deterioration had become more rapid. Acute pain had returned to the legs and wrists, despite continued treatment with prednisone, and general symptoms, including weakness, anorexia, and weight loss, were prominent. In addition local pain and tenderness over the lower thoracic spine suggested dissemination of the tumour to sites other than the lungs

In March the patient again entered hospital She was weak and dyspnœic, with limb and back pain, and a high intermittent fever, accompanied by severe rigors on most days There was now evidence of further subperiosteal bone formation in the right ulna Treatment with intravenous nitrogen mustard was ineffective. She died in May, just over a year after the symptoms of H P O.A. first appeared

Postmortem Findings

The body was slightly wasted, with diffuse pale brown pigmentation of the skin, clubbing of the fingers and toes, circumoral hirsuties, and a midline scar from the hysterectomy

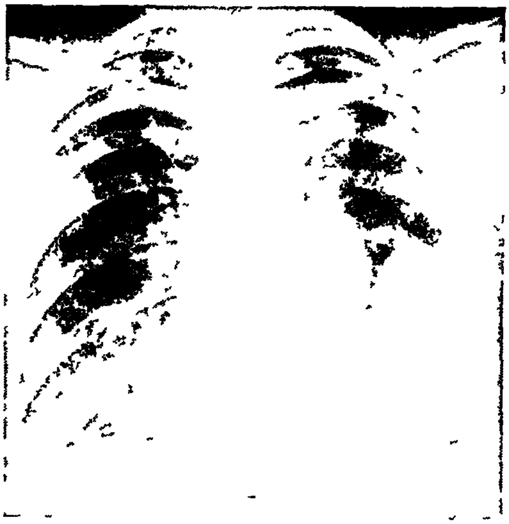

Fig 2—" Cannon-ball " metastases in lungs

There was no evidence of local recurrence of the uterine primary sarcoma other than a small nodule overlying the right ovarian vein Widespread, frequently necrotic, secondary sarcomatous deposits were found in both lungs (the largest measuring 5×10 cm) and invading the adherent parietal pleura over the left anterior basal segment. The visceral pleura, and larger pulmonary arteries and veins, were invaded by sarcomatous nodules from both lungs

Further sarcomatous deposits were present in one upper left hilar lymph-node, in the intestinal submucosa from stomach to colon, and in the liver, pancreas, right kidney, and suprarenals, although a substantial amount of normal suprarenal tissue remained Sarcomatous deposits were also found in the D11 and D12 vertebral bodies, and in the right femur

In addition there was a scar of an old posterior cardiac infarct, bilateral cystic mastitis, hyperostosis frontalis interna, and subperiosteal new-bone formation in the right femur and tibia The other long bones were not examined

Histology—The secondary sarcoma resembled the primary, showing various degrees of differentiation from slightly atypical spindle-cells to multinucleate giant-cell forms, with corresponding variability of myofibrils and reticulin fibres In several of the pulmonary deposits fine collagen fibrils had coalesced in some areas to form broad bands of mature collagen These scarred foci were found chiefly near the necrotic areas The lungs showed widespread and moderately severe stenosis and obliteration of respiratory bronchioles, with early centrilobular emphysema The anterior lobe of the pituitary (weight 0 8 g) showed vacuolation but no hyalinisation of the relatively infrequent basophil cells, the acidophil cells were increased

Discussion

Whatever the exact mechanisms involved in the production of H P O A, they are clearly not primarily dependent upon the type of pulmonary disease, though the prevalence and mode of presentation of H P O A differs according to the nature of the intrathoracic lesion

Relevance of Tumour Type

In nearly all collected series, bronchial carcinomas predominate as the tumour underlying H P O A, but this may merely reflect the increase in bronchial carcinoma in recent years, the incidence of H P O A is in fact small—probably less than 2% (Semple and McCluskie 1955) In contrast, other intrathoracic growths, notably fibrous growths of the pleura, are associated with H P O A relatively more often

In six cases of fibroma of the visceral pleura described by Price Thomas and Drew (1953) no less than four presented with joint symptoms Polley et al (1952) reported twenty-four cases of localised fibrous mesothelioma of the pleura of whom eighteen had articular symptoms, ten with the full changes of H P O.A.

Fibrosarcomatous metastases are more likely to cause H P O A than any other tumour which disseminates to the lungs But H P O A is rarely associated with hæmatogenous spread from a non-pulmonary source, though Mendlowitz (1942) points to the preponderance of sarcomatous deposits, particularly when derived from primaries in bone Metastatic sarcomas, though relatively less common, are much more often associated with H P O A than are metastatic carcinomas

Apart from secondary sarcomas, few secondary lung tumours have caused H P O A Isolated examples of H P O A have been seen in cases of pulmonary spread from primaries in breast, adrenal, and possibly parotid (cited by by Mendlowitz 1942)

Relevance of Anatomical Site and Rate of Tumour Growth

It has been suggested that the anatomical situation of the tumour within the lung is important, peripheral lesions being more prone to cause H P O A In addition, of course, the rate of growth must be slow enough to allow the bone changes to take place The histological characteristics of the tumours most likely to cause H P O A are not necessarily their most important feature

Treatment

Inevitably the approach to treatment must be empirical so long as the exact mechanism by which pulmonary lesions initiate H P O A remains obscure But it is of interest that after removal of a primary bronchial carcinoma in some patients with H P O A bone changes have disappeared, and, later, lung secondary deposits have arisen without return of H P O A No clear explanation can be offered for these observations, but it seems unreasonable to postulate that a primary bronchial carcinoma has inherently different properties from its seedlings

Steroids may be used palliatively when operative removal of the thoracic growth, or vagotomy, are impracticable, as in our patient

de Seze et al (1952) described the case of a man of 57 with severe pain in the limbs due to H P O A, who had a rounded opacity in the left chest He refused operation, and was treated with cortisone The pain disappeared within 5 days, only to return when the steroid was withheld Hammarsten and O'Leary (1957) reported significant relief of bone pain when cortisone was given to six patients with H P O.A

Semple and McCluskie (1955) emphasise that in H.P O A remission of joint symptoms may be spontaneous or may apparently follow radiotherapy to the lung tumour, in addition pain may disappear after the use of nitrogen mustard, corticotrophin, or gold Some of these forms of treatment are directed at the thoracic lesion, and others may act peripherally on the bones and joints Flavell's experience (1956) that vagotomy gives dramatic relief of bone pain suggests a neurogenic link in the causative chain.

Summary

A woman presented with symptoms of hypertrophic pulmonary osteoarthropathy (H P O A), and was found to have pulmonary metastases, 4 years after the removal of a uterine leiomyosarcoma

Tumour type is important in determining whether H P O A develops Although sarcomas are rare, H P O A is much more often associated with their pulmonary metastases than it is with carcinomatous metastases

Steroid therapy temporarily relieved her bone pain without affecting the progress of H P O A.

Rate of growth and situation in the lung may be the most important features of tumours in initiating H P O A

We should like to thank Mr Victor Lack and Dr N L Rusby, under whose care the patient was admitted, for their help with this paper, and for permission to publish

REVIEWING the modern biochemical predication of hepatolenticular degeneration, Warnock and Neill (1958) pointed out that the original syndrome, so clearly described by Wilson in 1912, has " become clouded by the progress of events ", and that in recent years more and more weight has been given to underlying biochemical anomalies as absolute criteria of the condition They conclude, however, that " laboratory evidence is seldom, if ever, definite enough to confirm the diagnosis, in isolated cases, without the presence of Kayser-Fleischer rings " The position is made even more difficult by reports of cases which show the cerebral morphological changes of Wilson's disease unaccompanied by structural liver disease This has led Brzezicki (1937) to use the term " cerebral Wilson's disease ", and is yet another indication of the difficulties which accrue from insisting on rigid " pigeon-holing " of diseases on the basis of an original and striking description.

Wilson's disease has become more clearly defined as a condition essentially associated with disordered copper metabolism and increased copper storage in the brain and other tissues (see Cumings 1959) But puzzling cases occur from time to time, and " it is important that cases which do not conform to the modern chemical criteria of Wilson's disease should be fully recorded " (Greenfield 1954) The following case, which presented a considerable diagnostic problem during life, is certainly not one of Wilson's disease as at present defined biochemically, but we thought the unusual transitional features should be recorded.

Case-report

CLINICAL HISTORY

The patient, a girl, was an only child born of healthy parents, when they were 28 and 26 The family history was irrelevant, and the mother had had no previous pregnancies

Fœtal and Newborn Period

Apart from troublesome vomiting, pregnancy was considered normal The fœtus presented as a breech, external version, attempted at 37 weeks, was unsuccessful, and the infant was delivered as a breech in hospital 5 days before the expected date Labour lasted 12 hours, towards the end the fœtus was distressed, and for a short time before delivery the fœtal heart was not heard Birthweight was 7 lb The mother was told that the infant had had a " rough time " Because of this the baby was kept in the nursery for the first 3 days, thereafter she was breast-fed for 6 weeks She seemed well during this time, and neither sucking nor swallowing was difficult

Later Development

The child sat up, with a straight back, at 7 months She pulled herself on to her feet and began to walk with support at 14 months Development was then delayed by whooping-cough, and not until 18 months did she walk unaided She pronounced single words at 15 months, and phrases at 2 years, speech was intelligible from the beginning She had measles at 4 years 10 months She never had an illness associated with excessive drowsiness or delirium

Development of the Illness

The parents had noticed from birth that the child had always been content to remain still She was never as adventurous as other children, and she did not play with them, because her legs were so clumsy—" as though she had two left feet " Because of this clumsiness, which did not improve as she grew older, specialist advice was sought at the children's department of the Royal Victoria Infirmary, Newcastle upon Tyne, when she was *6 years* old The clumsiness was evident when she ran, but no abnormal neurological signs were elicited

The clumsiness quickly became more striking, and she fell so often, that whilst on holiday at the age of *6 years 3 months* she was admitted to the Royal Aberdeen Hospital for Sick Children under the care of Prof John Craig for investigation. Her gait was ataxic, and she stamped on the ball of her left foot as she walked. The left hand and leg were slightly ataxic on formal testing There was no papillœdema, but, as a cerebral tumour was considered possible, ventriculography was performed by Mr W M. Nichols This showed no ventricular dilatation or displacement " Cerebellar degeneration " was diagnosed tentatively

When aged *6 years 8 months* the girl was seen at the Royal Victoria Infirmary by Prof Donald Court. She was unable to run or walk normally, and she could not hop, skip, or jump, she undressed slowly, having great difficulty with buttons and bows Her tendon reflexes were brisk, with bilateral unsustained ankle-clonus, and the plantar responses were equivocal She was thought at this time to have a mild ataxic form of cerebral palsy To our surprise, during the next year the child's symptoms steadily increased and the ataxia became worse in her right leg She was seen again at the age of *7 years 11 months* by Professor Court and Dr Henry Miller Walking was very difficult and slow, and she now turned her right foot inwards In the arms muscle-tone was variable, and occasional involuntary movements were seen All tendon reflexes were brisk, the right plantar response was extensor and the left was equivocal The diagnosis of torsion spasm was considered, but the involuntary movements and the recent deformities of posture were attributed to the late onset of choreoathetosis Aminoaciduria was now well marked, most aminoacids were present, including cystine The serum-copper was 104 μg per 100 ml

By the age of *8 years 2 months* the child could not move individual fingers, and power was diminished in both hands She could make all speech sounds normally in isolation, but some slurring and weakness of consonants appeared when she tried to speak quickly or when she was tired There was some weakness of the lips and palate At *8 years 4 months* she was given primidone 45 mg t d s , as a result, it seemed, her voice became stronger and her walking steadier Boots, a short leg calliper, and an outside T-strap were ordered to correct the position of her right foot

In view of the steady progression of symptoms and the baffling nature of the illness, arrangements were made for the child to be admitted to the National Hospital, Queen Square, under the care of Dr Arnold Carmichael Meanwhile she had a number of violent headaches (2 or 3 a day) which frightened her and made her cry out, but which lasted only a few minutes

While in the National Hospital (aged *8 years 9 months*) she had three seizures in which her head jerked to the right Her eyes also turned to the right, and the right angle of her mouth twitched Her right arm made clonic movements, but consciousness was not lost An air-encephalogram was within normal limits Electroencephalography showed a significantly fast rhythm in the left temporal region, but no evidence of a localised lesion Dr Carmichael agreed that the signs were those of cortico-spinal degeneration of unknown ætiology The patient was discharged from hospital, taking primidone 250 mg t d s , which controlled her seizures completely

At *8 years 11 months* there was a rapid deterioration. Ataxia and weakness increased, tremor, drowsiness, and a right lower-motor-neurone facial weakness, with deviation of her tongue to the right, developed The child was admitted to the children's department of the Royal Victoria Infirmary, where primidone was thought to have caused her rapid deterioration When this drug was discontinued she improved rapidly, and her cranial nerve palsies disappeared almost completely Variable hypotonia was again found, but no torsion spasms were seen She was given phenobarbitone gr $^1/_2$ b d. and sodium phenytoin gr $^3/_4$ b d

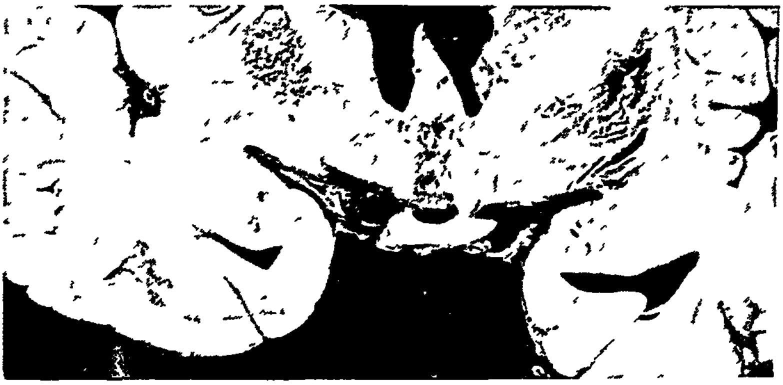

Fig 1—Coronal section at level of optic chiasma showing bilateral cavitation of lentiform nucleus

On returning home she was unable to walk unaided, but she seemed happy to sit, lacking the inclination to do anything Her speech became so weak that at times it was barely audible Often it was unintelligible By the age of *9 years 2 months* walking was impossible She had difficulty in swallowing, first solids and then fluids She had frequent seizures which could not be controlled by anticonvulsant therapy 48 hours before death she vomited repeatedly, and during the last 24 hours she seemed to have severe spasms of abdominal pain. She died at the age of *9 years 3 months*

POSTMORTEM FINDINGS

Necropsy was performed 6 hours after death The height was normal (4 ft. 2 in), but the body weighed only 13 kg (average 26 kg) There was a growth of very fine hair over the entire body but no other external abnormalities The hands were fixed in a curious " athetoid " position

The tongue, pharynx, and œsophagus showed no significant abnormalities The stomach contained some " coffee-ground " material without evidence of ulceration or other source of bleeding

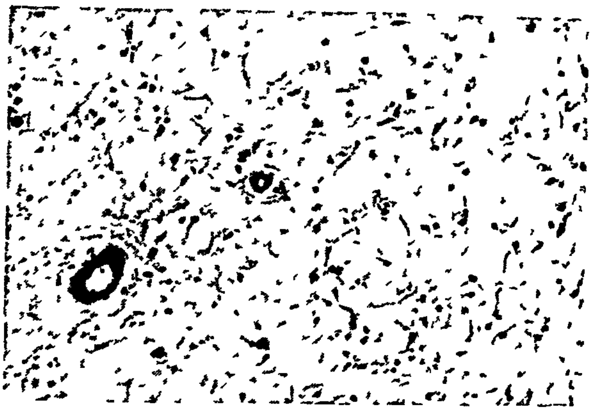

Fig 2—Left putamen showing open meshwork of astroglial cells with disappearance of nerve-cells (Hæmatoxylin & eosin ×129)

The liver weighed 500 g (average 736 g) and was pale chocolate-brown Section showed no macroscopic evidence of cirrhosis, and this has been confirmed histologically All other viscera were normal

The brain weighed 1300 g (average 1273 g) and showed no external abnormality The spinal cord and the femoral and ulnar nerves all appeared normal

Nervous System

On sectioning the brain, softening with cavitation was found in the putamen on both sides, extending forward into the head of the caudate nucleus and to some extent medially into the globus pallidus, especially on the right (fig 1) Because the head and body of the caudate nucleus was small, the lateral ventricle, especially in its anterior horn, was a little enlarged, and small ependymal granulations were visible No naked-eye changes were seen in sections of the brain-stem or spinal cord.

Blocks of tissue were taken from the region of macroscopic degeneration on both sides to include caudate and lentiform nuclei, thalamus, and subthalamus, from the frontal, motor, and occipitoparietal cortex of both sides as well as Ammon's horn, and from the mid-brain, medulla (at midway level), and spinal cord (at c5, mid-thoracic, and L1 levels) The tissues were embedded in paraffin and stained with hæmatoxylin and eosin, van Gieson's stain, phosphotungstic acid hæmatoxylin, and by Loyez and Holzer's method We had considerable difficulty in obtaining adequate frozen sections through the gross lesion in the putamina, but its margins were examined after being stained with Scharlach R and hæmatoxylin

Microscopical examination showed that lesions were more widespread than appeared to the naked eye, but of the same general nature There were more in the putamen than anywhere else Nerve-cells, both large and small, were much

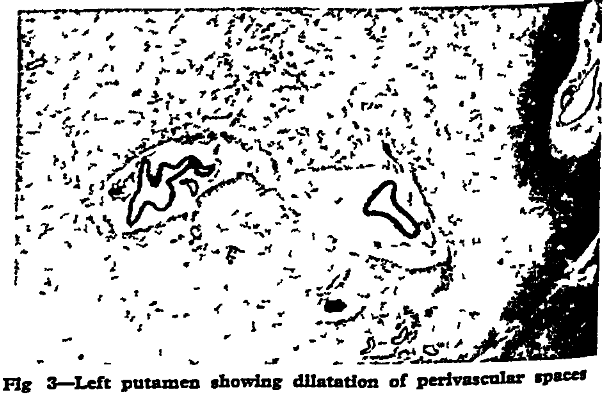

Fig 3—Left putamen showing dilatation of perivascular spaces (H. & E ×13)

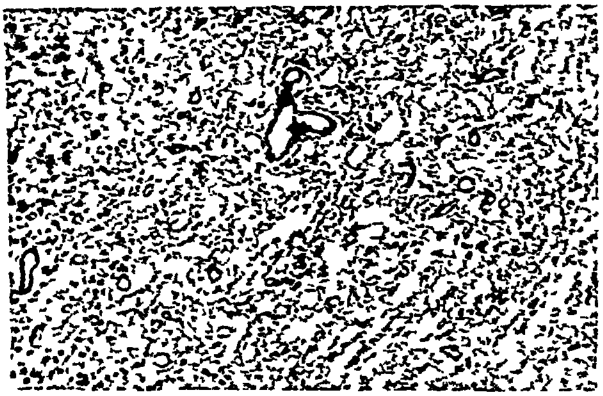

Fig 4—Subthalamic nucleus showing spongy state, prominent capillaries, and paucity of nerve-cells (H. & E. ×81)

reduced in number, and those remaining were almost devoid of Nissl substance. The whole putamen stood out clearly on low-power examination because it was pale and transparent, having been replaced by a loose spongework of glial tissue in which capillaries were numerous and prominent. There was no dense gliosis, the glial open meshwork was loose and had presumably contained gelatinous fluid (fig 2) Gliosis was well defined around many blood-vessels. Despite careful search no Alzheimer glial cells were recognised, though one or two astroglial nuclei were larger than normal No Opalski cells were seen. A striking feature was the great dilatation of perivascular spaces around the vessels in the putamen (fig 3) No myelinated fibres remained in the putamen, but the globus pallidus was relatively little disturbed. Copper could not be demonstrated histochemically in these lesions

COPPER ESTIMATIONS

Tissue	Copper content (mg. copper per 100 g dry brain)	Water content (%)
Cerebral white matter	4·03	69·6
Cerebral cortex	3 34	84·5
Basal ganglia	2·09	74·5
Cerebellar white matter	2·95	69·6
Cerebellar cortex	1·58	83·6

The above changes extended slightly into the outer part of the globus pallidus especially on the right, but did not affect the claustrum. A few compound granular corpuscles infiltrated the adjacent fibres of the pyramidal tract which themselves appeared intact. The amygdaloid nucleus and cornu ammonis were not affected on either side Similar changes of slightly lesser degree were found in the subthalamic nucleus of Luys (fig 4) and in the substantia nigra Small scattered areas in the cerebral cortex, especially the parietal and temporal regions, also showed minor changes, these were mainly in the more superficial layers of the cortex and were not noticeable to the naked eye (fig 5)

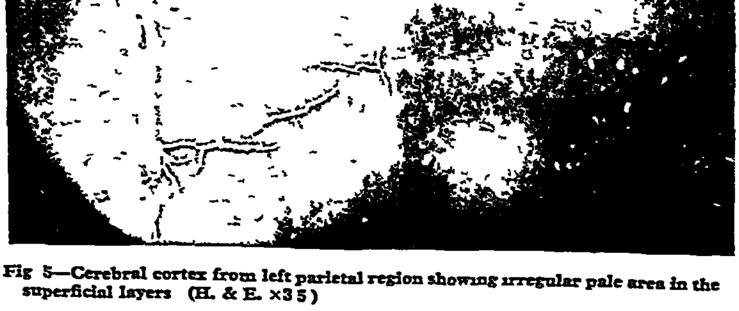

Fig 5—Cerebral cortex from left parietal region showing irregular pale area in the superficial layers (H. & E. ×3 5)

They formed isolated islands, and had much the same microscopic appearance as the main lesion in the putamen.

The white matter was unaltered. Occasional brightly sudanophilic compound granular corpuscles were clustered round small subcortical vessels, but these were few and scattered. Holzer preparations showed a moderate degree of subependymal gliosis in the lateral ventricles

In the medulla oblongata the perivascular spaces were dilated. The interior of the olive on both sides was spongy, many cells showed chromatolysis and vacuolation of their cytoplasm, and occasional enlarged naked astroglial nuclei, which resembled Alzheimer type-II cells, were found

The cerebellum was normal In the spinal cord only an occasional anterior-horn cell showed chromatolysis

Copper content—Prof J N Cumings of the National Hospital, Queen Square, carried out copper estimations on various parts of the brain. His results (see table) fall within the normal range, excluding the diagnosis of Wilson's disease as it has come to be defined biochemically

Discussion

The gross and microscopic lesions in the nervous system of this patient resemble those found in the brain in true (biochemically defined) Wilson's disease The term "hepatolenticular degeneration is more misleading than informative for it leads many to believe that the changes in the brain are limited to the lenticular nuclei" (Lichtenstein and Gore 1955) Neither Alzheimer nor Opalski cells were found in the present case, and their absence suggests that liver function had not been long deranged.

Brown (1957) has found that Alzheimer cells are by no means pathognomonic of Wilson's disease, being seen in many different conditions and in brains of patients without liver disease. He claims to have found them in considerable numbers in erythroblastosis fœtalis (premature), paralysis agitans, Huntington's chorea, tuberose sclerosis, Alpers' disease, Marie's cerebellar ataxia, multiple sclerosis, Krabbe's disease, cerebral arteriosclerosis, cerebral contusion, the border zone of glioblastoma multiforme, and in two normal brains He therefore suggests that though Alzheimer cells are more numerous when hepatic disease is present, they should not be regarded as characteristic.

It is difficult to know what significance should be attributed to the aminoaciduria found at the single examination of the urine made during life Dr A J Smith reported as follows

Partition paper chromatography on the patient's urine, on May 13, 1957 (i e , 15 months before her death), showed a well-marked aminoaciduria. The pattern was similar to that found in acute liver disease.

Urine from each of the patient's parents was examined on two occasions after her death. The first time both appeared chromatographically to have aminoacids at the upper border of normal, although their urinary aminonitrogen content was normal. But when the investigations were repeated both urines were normal.

The main interest of this case lies in the changes in the brain, which are similar to those found in Wilson's disease (but without Alzheimer or Opalski cells) There was no structural liver damage. Copper metabolism was not disordered Like that reported by Greenfield (1954), this case has anomalous features which do not readily fit into any scheme of classification

Greenfield's patient was a woman of 41 who presented an "unusual combination of Parkinsonism and intention tremor sometimes seen in hepatolenticular degeneration but rare otherwise" There was no Kayser-Fleischer ring and no aminoaciduria. At necropsy the liver was found to be cirrhotic. The caudate nucleus and putamen were shrunken Alzheimer glial cells were common. There was no abnormal copper storage in brain or liver Greenfield concluded that this case "may be classed as hepatolenticular degeneration, although it was atypical in several respects, but chemically it was entirely different. Cases like this are probably not very rare, but as the biochemical changes of Wilson's disease are recent discoveries they have not yet been reported. Their classification raises a difficult problem, since the biochemists exclude them from the category of Wilson's disease Meanwhile it is important that cases such as this, which do not conform to the modern chemical criteria of Wilson's disease, should be fully recorded"

The position is further complicated by reported cases of "Wilson's disease" without liver involvement All of these, reviewed by Eicke (1957), date from before the period of biochemical definition of Wilson's disease, hence one cannot be sure that they are indeed that condition Only the accumulation of further cases which are biochemically documented can clarify the issue Our case serves to underline the question raised by Greenfield (1954)—"Is hepatolenticular degeneration a clinicopathological entity?"

Summary

A girl, who died at the age of 9 years 3 months, had the morphological changes of "Wilson's disease" in the central nervous system without hepatic cirrhosis Copper metabolism was not disturbed but aminoaciduria was present She had no Kayser-Fleischer ring

This case cannot be grouped with Wilson's disease as biochemically defined at present

Our thanks are due to Prof Donald Court for permission to publish this case, to Prof J N Cumings for the copper estimations and for permission to publish table I, to Dr A J Smith for the urine chromatography, and to Mr C J Duncan of the department of photography for fig 5

FAVISM IN A CYPRIOT CHILD

N D Gower
M B Lond
SENIOR REGISTRAR IN PATHOLOGY

Eva Frommer
M B Lond, D C H
REGISTRAR IN PÆDIATRICS

EDGWARE GENERAL HOSPITAL, MIDDLESEX

Favism is a form of acute hæmolytic anæmia which occurs in certain sensitive subjects after eating broad beans Most cases are said to arise in persons of Sardinian ancestry (Luisada 1941), but the disease is quite widespread throughout the Mediterranean seaboard and islands (Marcolongo 1953) and has been recognised in Hebrew children (Robinson 1941) Owing to this racial predisposition favism is rarely seen in this country Two cases in Cypriot children in London were described by Diggle (1953) and another was recognised by Discombe and Mestitz (1956) At least one case has been seen in an English child, whose maternal uncle may have suffered from the disease (McCarthy 1955)

Favism is a serious disease, especially in children, in whom the mortality-rate may reach 8% or 10% (Luisada 1941, Marcolongo 1953) Renal impairment and lesions of the basal ganglia are occasional sequelæ (Marcolongo 1953) For these reasons, and because favism is preventable, we have recorded the following case, which also serves as a reminder that Cypriot children may suffer from red-cell defects other than the hæmoglobinopathies

Case-report

First Admission

A three-year-old boy, the second child of healthy Cypriot parents, was admitted to Edgware General Hospital on July 11, 1958, with a history of rapidly increasing pallor and the passage of dark-red urine for twenty-four hours The child had complained of pain in the neck and had vomited several times He had previously been fit except for recurrent sore throat There was no history of any familial disease

On examination the child was restless and obviously ill He was very pale and slightly jaundiced The temperature was 100°F, pulse-rate 132, and respiration-rate 28 per min The tonsils were enlarged and injected. A few small glands were palpable in the neck and left axilla The spleen and liver were not felt and there were no other physical findings of note A clinical diagnosis of acute hæmolytic anæmia, possibly due to streptococcal throat infection, was made

Investigations—Hæmoglobin 3 6 g per 100 ml (26%) White cells 15,300 per c.mm Blood-film showed many fragmenting cells and occasional microspherocytes A few myelocytes and normoblasts were present Platelets were plentiful Direct Coombs test negative, using Coombs serum at dilutions 1/5, 1/20, 1/80 Blood-urea 75 mg. per 100 ml Serum-bilirubin 4 mg per 100 ml The urine was almost black in colour and the deposit contained a few red cells and granular casts Spectroscopy showed the presence of oxyhæmoglobin and methæmoglobin Three throat swabs were taken in the first two days but none yielded *Streptococcus pyogenes* or other pathogenic bacteria on culture

Course and Treatment

The provisional diagnosis was revised to acute exacerbation of a congenital hæmolytic anæmia, but in view of the clear need for urgent blood-transfusion we decided to defer more extensive investigation until the patient was in remission Two bottles of compatible packed cells were transfused on the same day No difficulty was experienced with the cross-matching or transfusion of the blood. Although the Coombs test was negative 25 mg of cortisone was given intramuscularly, followed by 5 mg of prednisolone daily for six days In view of the apparent tonsillitis a course of penicillin was also given. The hæmoglobin level on the day following transfusion was 9 9 g per 100 ml and did not subsequently fall below this level Clinical improvement was rapid, hæmoglobinuria ceasing during the second day in hospital The blood-urea and serum-bilirubin levels fell to normal by the third day The spleen became palpable on the third day but had disappeared beyond the costal margin two days later The patient was discharged home on the eleventh day, looking very well, with a hæmoglobin level of 10 8 g per 100 ml and a reticulocyte-count of only 1% One month later his blood-picture was quite normal

The child was seen again three months later He was fit and lively, and no abnormality was found on physical examination

Investigations—Hæmoglobin 12 4 g per 100 ml (87%) Reticulocytes less than 1% The stained film showed no morphological abnormality of the red cells, in particular no spherocytes, target cells or macrocytes were seen The leucocytes and platelets were normal The osmotic fragility of the red cells was normal and incubation autohæmolysis (Selwyn and Dacie 1954) was less than 1% even without glucose With glucose added there was no detectable hæmolysis after forty-eight hours Acid hæmolysis test negative Red-cell potassium 82 mEq per litre Electrophoresis showed no abnormal hæmoglobin

We concluded that the child was unlikely to be suffering from even a mild congenital hæmolytic anæmia

The patient was seen again in January, 1959, as he had been unwell for a few days No abnormality was found on examination, but his hæmoglobin level was only 9 0 g per 100 ml.

Second Admission

He was readmitted to hospital on March 13, 1959 He had developed a sore throat several days previously and for twenty-four hours he had been passing dark-red urine Examination revealed no physical abnormality and the child was not nearly so ill as on his first admission Direct inquiry revealed that he had eaten broad beans, which had been purchased frozen, on the day before the onset of hæmoglobinuria We then discovered that this little boy did not like broad beans and had eaten them only twice before The first time was just before his serious episode of hæmolysis and the second time was a few days before he was seen in January, 1959, and found to be a little anæmic The diagnosis of favism was apparent The child made a rapid recovery without transfusion

Investigation on this occasion again failed to reveal any evidence of red-cell defect, but at a later date when the patient had a normal blood-picture (hæmoglobin 12 0 per 100 ml, reticulocytes 1 4%), we were able to show that his red cells behaved abnormally after incubation with acetylphenylhydrazine, using the method described by Beutler et al (1955), for the detection of " primaquine-sensitive " red cells This test was unequivocally positive, 80% of the patient's erythrocytes developing multiple small Heinz bodies, compared with 27% of the normal control

Discussion

Until recently favism was regarded as an " allergic " response to the proteins of broad beans, but Larizza et al (1958) have demonstrated an intrinsic red-cell defect in patients with favism, both during the active phase of the disease and after recovery This defect is identical with, or at least closely related to, the intrinsic abnormality found in patients in whom hæmolysis develops in response to primaquine, sulphonamides, and nitrofurantoin (" primaquine sensitivity " or " primaquine anæmia ") Beutler (1959) and others have shown that the erythrocytes of these patients are deficient in glucose 6-phosphate dehydrogenase These defective red cells can be most simply recognised by the characteristic pattern of Heinz-body formation produced in them by acetylphenylhydrazine treatment, or by their inability to retain glutathione (" glutathione instability ") after incubation with acetylphenylhydrazine (Beutler et al 1955, Beutler 1957)

The diagnosis of favism is not likely to present difficulty if the possibility is borne in mind, but in the absence of a history of eating broad beans it may be confused with a crisis of a congenital hæmolytic anæmia Earlier authors have denied the presence of spherocytes in favism, but their occurrence is recognised by Marcolongo, and our case could not be differentiated on morphological grounds alone from cases of congenital spherocytosis presenting with crisis The combination of suggestive peripheral blood findings, negative direct Coombs test and maintenance of the hæmoglobin level following blood-transfusion was thought to support the latter diagnosis, but the normal result of incubation autohæmolysis excluded congenital spherocytosis and most types of congenital non-spherocytic hæmolytic anæmia The diagnosis of favism was eventually made on the history of eating broad beans, supported by the demonstration of " primaquine sensitivity "

On theoretical grounds it seems possible that individuals who are subject to favism may develop hæmolytic anæmia in response to certain common drugs, although little evidence to support this idea can be found in the literature apart from Luisada's observation that quinine hæmoglobinuria is rather common in patients who have previously had favism Nevertheless favism is an indication of enzyme-defective red cells in a person, and its diagnosis may be as important as a warning to avoid certain drugs as it is a warning to abstain from broad beans

We are grateful to Dr M D Baber for permission to publish this case and to Dr Baber and Dr J L Hamilton-Paterson for advice in preparing the manuscript

CLINICAL PATHOLOGIST TO THE ROYAL VICTORIA HOSPITAL, BELFAST

Encouraging results have recently been reported in the treatment of disseminated mammary carcinoma with thiotepa (triethylene thiophosphoramide) combined with testosterone (Watson and Turner 1959) One of the recognised complications of this form of therapy is toxic marrow damage with peripheral pancytopenia This complication arose in a woman with widespread metastases from a mammary carcinoma who was treated with thiotepa and testosterone at the Northern Ireland Radiotherapy Centre

Animals exposed to otherwise lethal irradiation can be saved if injected with suspensions of hæmopoietic cells (Lorenz et al 1951, Porter 1957, Ferrebee et al 1958), under these conditions the injected cells " home to " and repopulate the depleted medullary cavities (Ford et al 1956) Marrow infusions have also been successfully used in patients with marrow failure resulting from either irradiation (Thomas et al 1959) or massive chemotherapy (Westbury et al 1959) It was decided therefore to attempt marrow-replacement therapy in this patient by injecting homologous hæmopoietic cells Since experiments have shown that the interactions between host and grafted homologous material are reduced if fœtal tissue is transferred (Barnes et al 1958, Uphoff 1958), suspensions of human fœtal liver were used

Case-report

Early in 1957 the patient, aged 43, noticed a lump in the upper outer quadrant of her left breast When first seen, in January, 1958, the entire breast was solid with tumour and fixed to underlying muscle, and enlarged lymph-nodes were easily felt in the left axilla and left supraclavicular region. A chest radiograph revealed some lymphangitic infiltration of the lung fields, but skeletal radiographs did not show evidence of bony metastases. Mammary carcinoma, with local infiltration and evidence of lymphatic and bloodstream spread, was diagnosed.

The patient was treated with 19-norandrostenolone phenylpropionate ('Durabolin') 25 mg. intramuscularly once weekly for 45 weeks. The response at first was good; in March the supraclavicular and axillary nodes were no longer palpable and no discrete tumour was felt in the breast. In September the left cervical lymph-nodes had recrudesced, and the tumour was adjudged refractory to testosterone therapy.

In November oral stilbœstrol therapy (20 mg. daily by mouth) was started, but this caused considerable systemic side-effects and had to be discontinued after 3 weeks. In January, 1959, the tumour was readily felt in the breast and a palliative course of X rays was given locally to the involved area. The tumour and cervical lymph-nodes responded well, but the general condition of the patient remained poor, and it continued to deteriorate over the next 8 months.

In September the breast contained a diffuse hard mass, a chain of fixed lymph-nodes extended from the medial end of the clavicle to the mastoid process, and skeletal radiographs showed widespread bony metastases. On Oct. 1 a 5-week course of testosterone propionate intramuscularly was started; the patient was given 1000 mg. weekly in five divided doses. 6 days after starting this therapy she was given an initial dose of thiotepa 15 mg. intramuscularly, which was not followed by any reaction. 2 days later a course of thiotepa 30 mg. on alternate days, to a total dosage of 255 mg., was started. Whilst having thiotepa and testosterone therapy the patient's general condition improved initially, the mass in the breast felt softer, the cervical lymph-nodes decreased in size, and her previously severe skeletal pain decreased. Before this chemotherapy the white-cell count was of the order of 8000–9000 per c.mm., and the platelet-count was 200,000–250,000 per c.mm. When the patient had had 45 mg. of thiotepa the leucocyte-count began to fall, but despite this evidence of marrow damage we decided to continue therapy in the hope of producing maximum effect on the carcinomatous deposits. When the course of thiotepa was completed the leucocyte-count was 1300 per c.mm., and the platelet-count had also fallen, to 82,000 per c.mm. Both these counts continued to fall; 11 days later the leucocyte-count was 200 per c.mm. and the platelet-count 40,000 per c.mm. These levels were maintained for a further 5 days—i.e., until the transfusion of fœtal cells. The hæmoglobin level before chemotherapy was 11·5 g. per 100 ml., and this also fell so that on Oct. 26 it was 7·9 g. per 100 ml. The patient was then given a transfusion of 2 pints of blood, but this raised the hæmoglobin level only very temporarily, which, 11 days later, had again fallen, to 6·3 g. per 100 ml.

Attempts were not made to aspirate bone-marrow because, in view of the severe thrombocytopenia, we thought the procedure might cause excessive hæmorrhage.

The patient's general condition remained reasonably good until the end of the course of thiotepa, but from then deterioration was quite rapid. On Nov. 6 she was very weak, with severe anorexia and vomiting; she had a septic lesion on her right forehead, and extensive bruising of her legs, and she had several small hæmoptyses. At this point she was given tetracycline 250 mg. q.i.d. and methyl prednisolone ('Medrone') 40 mg. daily by mouth.

Treatment with Hæmopoietic Cells

Next day (Nov. 7) the patient (blood-group A, CDE cde MN+ Le^a −ve S−ve K− Fy^a −ve) was given 2 pints of blood and 18 ml. of fœtal liver suspension.

The fœtal material had been obtained from a male fœtus of blood-group O, CDE cde, NS, K− Fy^a+, and stored at −78°C as described by Kay and Constandoulakis (1959). 3 ml. of fœtal material was thawed and injected into the drip at 10 A.M. at the rate of 1 ml. per min., and a further 5 ml. was injected at 11 A.M., at 6 P.M., and at 7 P.M. Chlorphenimamine maleate ('Piriton') 2 mg. was given by mouth hourly throughout the transfusion.

No untoward reaction followed, and the patient's general condition improved quite dramatically. Her temperature remained normal, she felt better, the anorexia and vomiting disappeared, and the septic lesion on her forehead rapidly healed. She made steady progress, and was discharged home on Nov. 23—i.e., 16 days after the fœtal liver transfusion.

The immediate response in her white-cell and platelet counts is shown in fig. 1. Repeated differential white-cell counts also showed a striking change. Before transfusion the circulating white cells were all mature lymphocytes. 2 days after transfusion the peripheral blood showed myelocytes 4%, metamyelocytes 2%, band forms 40%, neutrophils 34%, lymphocytes 4%, and monocytes 16%, and there were 2 normoblasts C per 100 white cells. The neutrophils were mostly young forms, only 10% showing three or more lobes in the nucleus. Over the next 2 weeks the granulocytic series remained preponderant in the differential white-cell count, but, while the proportion of mature neutrophils increased, the myelocytes and metamyelocytes disappeared from the peripheral blood. The rise in white-cell and platelet counts has been maintained, no readings below 4000 and 200,000 per c.mm. respectively having been scored since Nov. 25.

The last blood examination on Dec. 18 showed a white-cell count of 7400 per c.mm., with a differential count of metamyelocytes 2%, neutrophils 78%, eosinophils 2%, lymphocytes 12%, and monocytes 6%, and the platelet-count was 285,000 per c.mm. The neutrophils were studied for nuclear drumstick appendages, and counts were made according to the method described by Kosenow (1956). The results were: Nov. 11, 14, and 16 male, Nov. 20 indefinite, Nov. 25 indefinite but probably female, Nov. 30 and Dec. 3 definitely female.

Immediately after transfusion and injection of hæmopoietic cells the hæmoglobin level rose to 8·6 g., at which it remained for the next 16 days (fig. 2). Reticulocyte-counts were done frequently, and the counts remained under 2% until the 8th day after transfusion; from then the proportion gradually increased until it reached 9·5% on the 16th day. From this day the hæmoglobin level rose sharply; 4 days later it was 10·4 g. per 100 ml., and the reticulocyte-count was 2%. 5 days later the hæmoglobin level had fallen to 9·8 g. per 100 ml., and the reticulocyte-count was now 9%. Since shortly after this time the hæmoglobin level has been above 10 g. per 100 ml.; the last time the peripheral blood was examined (Dec. 18) the hæmoglobin level was 10·4 g. per 100 ml. and the reticulocyte-count was 1·5%.

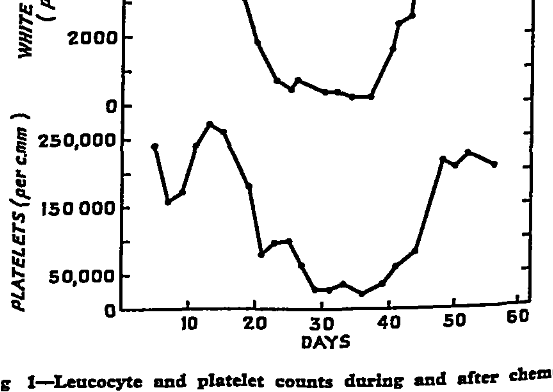

Fig. 1—Leucocyte and platelet counts during and after chemotherapy, and the response to fœtal liver suspension.

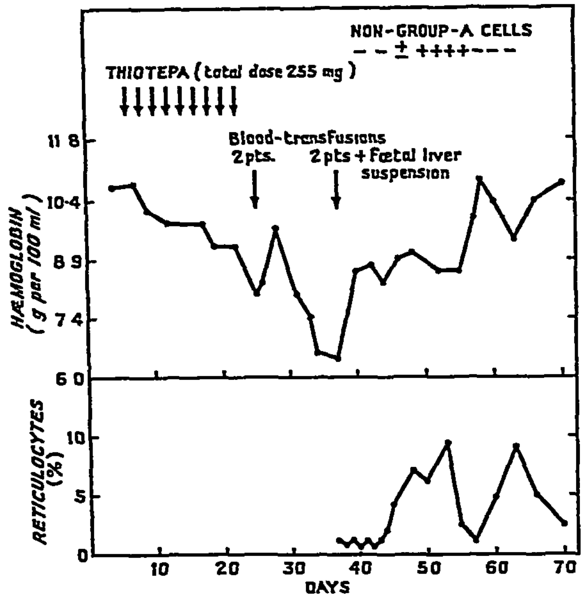

Fig 2—Hæmoglobin level during and after chemotherapy, and the reticulocyte-response to fœtal liver suspension

Differential agglutination of the red cells, using the modification of the Ashby technique described by Constandoulakis and Kay (1959), was done at 3-day intervals after transfusion, and showed that non-group-A cells were present 10, 13, 16, and 19 days after transfusion On and since the 22nd day, however, this technique has not shown any non-group-A cells

Attempts to aspirate marrow from the iliac crest were made on the 6th, 10th, and 14th days after transfusion. At the first two attempts no marrow was obtained. The third specimen showed a moderately cellular marrow, with active erythropoiesis which was normoblastic in type, and the relative proportion of proerythrocytes and normoblasts types A, B, and C was within normal limits Granulopoiesis was active, megakaryocytes were present and undergoing normal maturation.

Radiographs of the pelvis and lumbar spine on Nov 19 showed striking regression of the bony carcinomatous deposits

Discussion

In cases reported by Watson and Turner (1959), which were treated with combined chemotherapy as described above, marrow damage was often observed The number of circulating leucocytes fell to 13% of the pretreatment level (average 45% in twenty-three patients) Subsequent recovery without marrow treatment occurred within 31 days (average 11 6 days) Watson and Turner also described two cases treated with thiotepa alone in which the leucopenia persisted until they died 3 months after treatment.

More recently Gurling (1959) has reported toxic marrow damage in previously hypophysectomised patients with active mammary carcinoma who were treated by more frequent smaller doses of thiotepa. He considers that when the circulating leucocytes drop below 3000 per c.mm., or the platelet-count below 140,000 per c.mm , the drug should be withdrawn.

We thought that, in our patient, the severe anæmia (Hb 6 3 g per 100 ml.), leucopenia (200 per c mm.), and thrombocytopenia (40,000 per c mm.) which persisted for 16 days after the chemotherapy was stopped made immediate spontaneous marrow recovery unlikely We also hoped that the intense chemotherapeutic regime might have depressed the patient's immune mechanisms sufficiently to enable her to accept a graft of homologous tissue Hence we decided to try the effect of hæmopoietic tissue transplantation

The response to the fœtal liver transfusion was immediate and striking The patient's anorexia and vomiting disappeared within 36 hours, a septic lesion on her forehead rapidly healed, and her general condition steadily improved A parallel improvement was seen in the hæmatological findings, within 36 hours of the injection of hæmopoietic cells primitive granulocytes and erythroblasts appeared in the previously agranulocytic peripheral blood The hæmoglobin level was maintained after transfusion, the leucocyte and platelet counts rose, and the pattern of the differential white-cell count changed

There is little doubt that the transfused fœtal cells lived and matured in this patient for a time 4 days after transfusion the circulating neutrophils were of male (donor) type, and a similar result was obtained 5 days later On and since the 18th day, however, the circulating neutrophils have been of female (host) type. Examination of the peripheral blood for erythrocytes which were not of the same group as the host (group A) also showed that the transfused fœtal erythroblasts had matured, and that these cells were released into the peripheral circulation Non-group-A cells were demonstrated in the peripheral blood 10, 13, 16, and 19 days after transfusion, and their number reached a *maximum on the 16th day* On the same day the reticulocyte-count reached a peak of 9 5% and shortly afterwards the hæmoglobin level rose sharply (fig 2) We think that this reticulocytosis indicated activity of the transfused fœtal erythropoietic cells 5 days after the reticulocyte-count was 9 5% the hæmoglobin level reached a peak of 10 8 g per 100 ml and the reticulocyte-count had fallen to 2% This hæmoglobin level was not maintained, falling over the next 5 days to 9 8 g per 100 ml Simultaneously the reticulocyte-count rose to 9%, the peripheral blood was again examined for cells of a different group from the host, but this time none were found We think that this second reticulocyte peak indicates activity of the host erythropoietic cells

The reversal in sex of the circulating neutrophils from male (donor) to female (host), and the absence of non-group-A cells from the 22nd day after transfusion, both suggest that the fœtal graft was not permanently accepted Thus the patient showed chimærism for only some 3 weeks, but concomitantly with rejection of the fœtal graft her own marrow recovered and resumed hæmopoietic function

The patient still remains well Her left breast contains a soft diffuse mass which probably represents fibrosis resulting from radiotherapy, the cervical and supraclavicular lymph-nodes are no longer palpable, and skeletal radiographs show much improvement in the bony metastases The peripheral blood-picture too is satisfactory, and the severe toxic marrow failure following chemotherapy seems to have been reversed successfully

Our evidence suggests that the transplanted hæmopoietic tissue matured and survived in this patient for a time, and that its rejection was followed by restoration of normal marrow function in the host These findings should encourage the treatment of other cases of advanced cancer by chemotherapy in maximal dosage, since toxic hæmopoietic side-effects might, as in this case, be reversed

We should like to thank Dr H E M Kay, of the Royal Marsden Hospital, London, S W.3, for kindly supplying the fœtal material, Mr A Lamont and Mr D Boyd for technical help, and the nursing staff at Quinn House, Royal Victoria Hospital, Belfast, and the

Northern Ireland Radiotherapy Unit for their cooperation We are indebted to the British Empire Cancer Campaign and the Northern Ireland Hospitals Authority for financial help

A METHOD OF RECORDING SMALL MOVEMENTS

GEOFFREY RUSHWORTH
M A, B M Oxon
NUFFIELD RESEARCH OFFICER AND LECTURER IN MEDICINE, JESUS COLLEGE, OXFORD

ROBIN WILLISON
M.A, B M Oxon, M R C.P E
CLINICAL RESEARCH FELLOW, MEDICAL RESEARCH COUNCIL

From the Neurological Research Unit, The Churchill Hospital, Oxford

THE most difficult task in the electrical recording of biological phenomena is often that of finding a suitable transducer This paper is a preliminary report of our experience with a type of transducer which has recently become available* and which we find very valuable for recording tremor It also has other applications including its use as a convenient and simple means of recording the arterial pulse

The transducer is a titanate ceramic which exhibits a pronounced piezoelectric effect We have used the material in the form of discs 2 in and 1 in. in diameter and 0 02 in thick. These were constructed by the manufacturer to respond to bending by using the two thin discs sandwiched on each surface of a central brass foil This is a convenient way of producing a highly sensitive transducer of large capacity

The discs used are oppositely polarised (part no CS 648) The outer surfaces are silver-plated and may have connections soft-soldered to them if care is used The inner surfaces are applied to a brass foil, a portion of which protrudes to form a lead The discs may be obtained polarised in two ways so that deformation produces a charge between the outer surfaces, or between these and the central foil

The capacity of the larger (2 in) disc is 72,000 pf Pen deflections of 1–2 cm are easily obtainable with the present equipment Because the ceramic generates a charge it is difficult to give figures for output which have any comparative value However, the maximum overall gain of the two amplifiers is 1 cm per deflection for 0 005 microampere current in the input circuit At the pressures usually produced by tremor the output of the ceramic is of the order of 10–50 mV into an input load of 10,000 ohms

In practice the performance has been satisfactory for our purposes when the ceramic has been connected to the input of a direct-current (D C) two-transistor push-pull amplifier designed for us by Dr F D Stott† This leads to an ink-writing oscillograph, Ediswan, which is driven by Ediswan R 2251/2 D C. amplifiers The records presented here were made with this instrument. However, the ceramic disc may also be connected directly to a standard D C oscillograph such as the Nagard D T 103 where this type of display is indicated

Tremor

The physiological tremor of voluntary movement in man was originally investigated by Schafer, Canney, and Tunstall (1886), Griffiths (1888), Herringham (1890) Marshall and Walsh (1956) used an accelerometer valve (Mullard type DDR 100) to record tremor but this valve is no longer available In our recordings of tremor, the ceramic disc (2 in) lies on a pad of methylcellulose foam and the index finger is rested lightly on the centre of the disc Figs 1 and 2 show tremor recorded from the index finger with (1) the arm supported only by the shoulder-joint, and (2) the wrist supported on a firm surface The

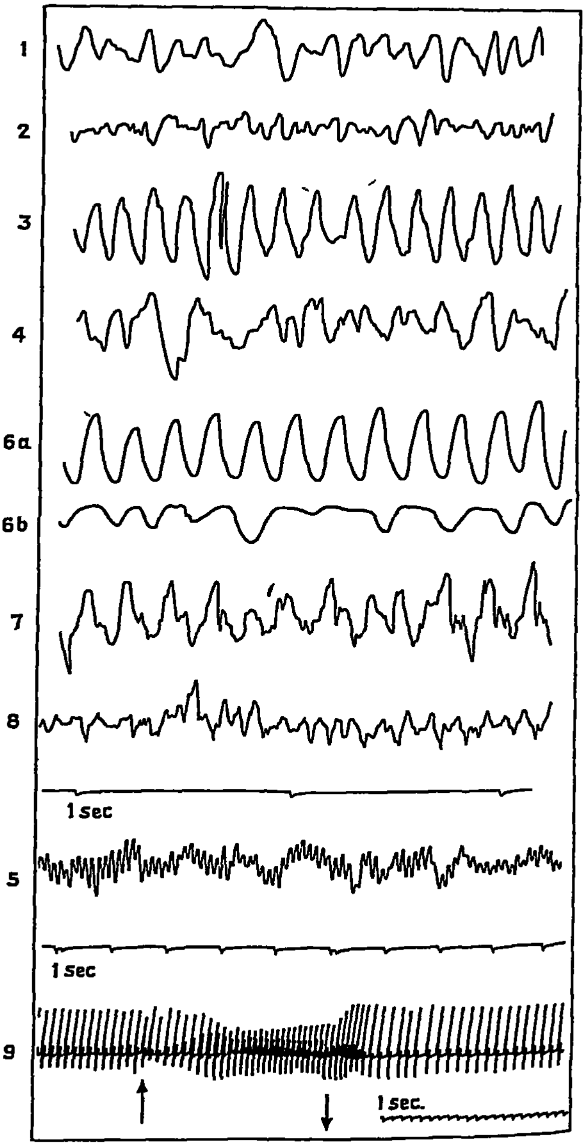

Fig 1—Tremor recorded from index finger, wrist free
Fig 2—As fig 1, but wrist supported
Fig 3—As fig 1 Parkinson's disease
Fig 4—As fig 1 Intention tremor in familial ataxia
Fig 5—As fig 1 Familial tremor N B slow paper speed
Fig 6a—Voluntary repeated rhythmic flexion of index finger in normal subject.
Fig 6b—As fig 6a, from patient with spastic ataxia, multiple sclerosis
Fig 7—As fig 6a, with transducer applied over muscle.
Fig 8—As fig 7 Maximal voluntary effort.
Fig 9—Transducer over brachial artery Valsalva manœuvre Arrows indicate duration of straining

---

* Manufactured by Technical Ceramics Ltd, Wood Burcote Way, Towcester, Northants

† Dr F D Stott, PH.D, a member of the external staff of the Medical Research Council, at the Churchill Hospital, Headington, Oxford

tremor-rate with the wrist supported is slightly greater, and the amplitude less, than without support Figs 3–5 were obtained, using a similar technique, from a case of parkinsonism (fig 3), a case of familial ataxia (fig 4) and a case of familial tremor (fig 5) As the amplifier gain in all these records (and subsequent tremor records) was approximately the same, the amplitudes of the tremors are comparable

Voluntary Movement

Fig 6 shows the production of rhythmic movement by a normal subject (a) and by a patient (b) suffering from multiple sclerosis with intention tremor, with spastic weakness of the hands without posterior column loss The instruction to the subject is to " press your finger repeatedly on the disc as evenly and rhythmically as you can "

When one is recording from the belly of a muscle, the disc is secured by an 'Elastonet' bandage wrapped gently round both disc and arm The disc is centred on the active part of the muscle, this is determined by palpation and maximum response of the disc. Fig 7 shows repeated small movements of the index finger, and fig 8 shows the record obtained with isometric maximal voluntary contraction of finger flexors

Pulse recording is most easily performed with a bender type strain gauge (Technical Ceramics type B 1), (a strip of ceramic) but a disc of 1 in diameter has also been used successfully This is secured over the brachial pulse in the cubital fossa with adhesive cellulose tape and the arm is extended Fig 9 shows a recording of the Valsalva manœuvre.

Summary

The ceramic transducer described is small, compact, and easily applied to surfaces In addition its output is high and linear with a long time constant These features suggest that it will have many applications in biological recording systems

The expenses of this development were in part defrayed by a grant from the National Fund for Poliomyelitis Research

Medical Societies

HEBERDEN SOCIETY

Corticosteroids and Arthritis

AT a meeting held at the West London Hospital on Feb 26 with Dr F DUDLEY HART, the president, in the chair, Dr P S DAVIS compared some results of long-term corticotrophin treatment of rheumatoid arthritis with those of oral corticosteroids Daily subcutaneous injections of corticotrophin gel were given to 40 patients who had not improved with rest and salicylates, and dosage was thereafter adjusted according to the clinical response and the 17-hydroxycorticosteroid output. All the patients were followed for at least two years Treatment was discontinued in 6 because of side-effects, in 7 because of acquired resistance, and in 6 because of complete remission Assessed by the strength of grip, the erythrocyte-sedimentation rate, and radiological appearances, the results compared favourably with those obtained with prednisolone in the Medical Research Council/Nuffield Foundation prednisolone-analgesic trial[1] Preliminary results also indicated that corticotrophin gel caused a fall in the titre of the Rose-Waaler test in an appreciable proportion of patients, in contrast to the tendency of the titre to rise with prednisolone therapy The relative ease of withdrawal of therapy when necessary was another factor in favour of corticotrophin gel, and injection sepsis had been negligible

Dr O SAVAGE reported on side-effects during long-term corticosteroid therapy in 910 cases of rheumatoid arthritis at eight centres The commonest were facial rounding, usually not severe, " dyspepsia ", with an incidence of 32%, came next, and peptic ulceration was put at 7% Hypertension occurred in about 13%, but in the majority of these it was not severe and only rarely was it necessary to withdraw the steroids Other side-effects (including arteritis, peripheral neuritis, fractures and collapse of vertebræ, bruising, and mental changes) were seen in less than 5%

Reviews of Books

Isolated Pulmonary Stenosis

JORGEN FABRICIUS, University Hospital of Copenhagen Copenhagen Ejnar Munksgaard 1959 Pp 203 Dan Kr 30

ISOLATED pulmonary stenosis, although far from the commonest of congenital cardiac abnormalities, is a lesion of great interest, for it was one of the first to be treated by direct surgery, and it is perhaps, of all congenital heart lesions, the one most accessible to assessment by special investigation Its emergence, in twelve years, from obscurity, when even its existence was doubted by eminent cardiologists, has been remarkable Despite the many papers already available on the subject, this monograph is a valuable addition

Small, elegantly produced (but paper-covered), it records a study of 75 cases, all confirmed by cardiac catheterisation, and of which 23 were treated surgically Probably no other series yet reported has been so completely and critically studied and documented The value of the work is greatly enhanced by a thorough and critical analysis of the literature (the bibliography contains about 450 references)

Apart from a few minor vagaries, which presumably have crept in during translation, the style is precise yet readable, and conveys much information in few words The tables and figures are well selected, clear, and informative

It is perhaps a disadvantage that a large proportion (33 of the 75) of the patients had only *mild* stenosis (defined here as a right ventricular pressure less than 60 mm. Hg), and that only 14 had *severe* stenosis (defined as a right ventricular pressure greater than 120 mm Hg) This has enabled the author to delineate clearly the picture of moderate and mild stenosis, but only to sketch roughly that of the surgically more important severe stenosis This defect is, however, minor, and the monograph can be warmly recommended

A Biochemical Approach to Pathology

M J R DAWKINS, M R C.P, junior lecturer in pathology, University College Hospital Medical School, K R REES, M SC., PH.D, senior lecturer in chemical pathology, University College Hospital Medical School London Edward Arnold 1959 Pp 128 18s

As biochemical information grows, it is becoming increasingly possible to express cell activity in terms of chemical reactions Research in pathology has taken full account of this trend, but few of the advances have reached the standard textbooks This book intends to offer the general reader what is otherwise to be found only in scientific journals or monographs, where it is often in highly technical language requiring specialised knowledge for full understanding

An introduction pays tribute to Sir Rudolph Peters, who first formulated the concept of a biochemical lesion. He was able to correlate the pathology of vitamin-B_1 deficiency and of fluoroacetate poisoning with failures in single enzyme reactions Many will be aware of the role of the vitamin in the decarboxylation of pyruvic acid, but they may find in this book for the first time a clearly written description of the jamming of the citric-acid cycle when fluoroacetate combines with oxaloacetate to form fluorocitrate, which then inhibits the essential enzyme, isocitric dehydrogenase or aconitase

The chemical reactions of the cell do not proceed in isolation but in dynamic equilibrium, so that interference with one will affect the whole integrated system. Block of one energy-producing mechanism may affect all energy-producing reactions and cause immediate death In such case the pathological changes are not specific, because there was no time for their development Block of a side-reaction not immediately vital will disturb the integrated pattern and alter the behaviour of the cell Disease would then represent a change in cellular metabolism brought about by pathogenic agents The book describes reactions observed in water-soluble extracts and in " breis " which contain small particulate matter, and discusses cellular organisation and the different parts taken in chemical activity by mitochondria, microsomes, nuclei, cytoplasm, and cell wall There are some excellent graphs and remarkable photographs Dr Dawkins also describes the action of poisons, endogenous and exogenous, and of bacterial toxins, and outlines the effect on cellular metabolism of deficiency in vitamins, trace elements, and essential aminoacids The role of D N A in protein synthesis and the relation of this process to the mode of gene action are explained in connection with the inborn errors of metabolism The biochemical changes in growth, both normal and in tumours, are briefly but clearly summarised.

This book is dedicated to Sir Roy Cameron and is a worthy tribute to his progressive teaching of pathology as well as to University College Hospital Medical School from which so many pioneering contributions on this subject have come

Back-View

SIR HAROLD MORRIS, Q C London Peter Davies 1960 Pp 244 25*s*

Thomas Fuller held that " Commonly, physicians, like beer, are best when they are old, and lawyers, like bread, when they are young and new " By this dictum, Sir Harold Morris, who cheerfully acknowledges eighty-three years, is long past his best and it needs a biography as youthful and vigorous as this to prove that the eminent divine was sometimes wrong in his generalisations

Sir Harold's first eight chapters are those of greatest interest to a medical reader, for they are largely concerned with his father, Sir Malcolm Morris, who was one of the first physicians in this country to specialise in dermatology These pages describe several unusual cases, and some distinguished patients Sir Malcolm was knighted after his successful treatment with radium of a small tumour under Edward VII's left eye A colleague who had previously been consulted lost the Royal patronage abruptly, when an attempt to destroy the lesion by electrolysis was short-circuited by a gold chain the King wore about his neck. Conan Doyle was a close friend of Sir Harold's father and he throws fresh light on how the character and background of Sherlock Holmes evolved

The remainder of the book deals with the author's experiences at the Criminal Bar Yet it is in the highest degree improbable that anyone—doctor or patient, barrister or plaintiff—who once begins to read will desist until he has consumed it all

The Anti-globulin (Coombs) Test in Laboratory Practice

I DUNSFORD, PH D, principal scientific officer, National Blood Transfusion Service, Sheffield, JEAN GRANT, F R.C.P E, director, National Blood Transfusion Service, Oxford. Edinburgh Oliver & Boyd 1959 Pp 120 12*s* 6*d*

A CONSIDERABLE literature has accumulated in the fifteen years since this test was introduced to hæmatological laboratories, and many variations of the original technique have been suggested This essentially practical handbook sets out in minute detail the techniques the authors now think best This practical instruction is preceded by a short account of the theory of antibody-antigen reactions and of the historical development of the technique The difficulties and false reactions met with in regular use of the test are fully discussed, and there is a description of applications in fields other than blood-grouping and hæmolytic serology This little book is a useful account of current techniques, and although refinements of technique go on all the time, it is valuable to have a standard that need not be altered until some major rearrangement is necessary

Low Intensity Radium Therapy

CHARLES L MARTIN, M D, F A C R, clinical professor of radiology, JAMES A MARTIN, M.D, F A C R, assistant professor of radiology, South Western Medical School, University of Texas, Dallas London J & A Churchill 1959 Pp 277 90*s*

THIS volume is written by father and son, whose work over the past thirty years provides the material for the book, and as the title suggests, their therapy has evolved round interstitial radium techniques

There are two parts to the book. Part 1 deals with technical considerations, including a very readable opening chapter on the history of radium—a novel in itself The system of dosage as evolved by Edith Quimby is described it is easy to comprehend and simple to apply, and, as the authors remark, the good results seem to justify this plan. Part 2 is concerned with clinical material, presented in case-history form, and lavishly illustrated with pre- and post-therapy photographs and a diagram to show the radium implant pattern for all cases There are over 100 illustrations, not counting an excellent colour atlas

To most therapists in this country, brought up on the Parker-Paterson dosage system, many of the implants may seem strange, but the authors are clearly artists in their work, and the justification of their work is in their excellent results Very few people still treat carcinoma of the cervix with radium needles, and implantation of the intercostal spaces after radical mastectomy for carcinoma of the breast cannot have many disciples left

This is a very readable and stimulating book, but the student should hesitate before quoting from it, in case his examiners object to some of its " heresy "

British Surgical Practice (*Surgical Progress 1959* London Butterworth 1959 Pp 479 52*s* 6*d*)—The 9th progress volume of *British Surgical Practice* is of particular excellence in a series which is well known for its quality It follows the usual arrangement, consisting of 20 articles reviewing various aspects of surgery, each followed by abstracts of the relevant outstanding papers of the previous year Sterilisation by heat, peptic ulcer, partial hepatectomy, chronic pancreatitis, rectal surgery, parotid tumours, endocrine surgery, breast cancer, amputations, and flexor tendon injuries are the titles of perhaps greatest interest to general surgeons, but orthopædic, gynæcological, neurosurgical, ophthalmological otological, and radiotherapeutic topics also receive attention, and an article on progress in the casualty department brings up the rear The " noter-up " keys the contents of this and preceding progress volumes to the chapters in the original work For any surgeon who finds difficulty in keeping up with the literature (another way of saying all surgeons) this volume is prescribed reading, and it is to be hoped that Sir Ernest Rock Carling and Sir James Paterson Ross will not find tedium in the repeated congratulations and thanks of surgeons for the excellence of their editing

Cancer in Families (Cambridge, Mass Harvard University Press, for Commonwealth Fund London Oxford University Press 1959 Pp 76 20*s*)—This monograph by Prof Douglas P Murphy, of the University of Pennsylvania, and Dr Helen Abbey, of Johns Hopkins, reports an investigation into the incidence of cancer in relations of individuals with breast cancer 200 families were involved and the survey was of necessity retrospective Data were obtained by interview, and three of the four interviewers were trained nurses This serious statistical study revealed no detectable familial tendency towards cancer

THE LANCET

LONDON 19 MARCH 1960

Orthostatic Hypotension

ORTHOSTATIC hypotension may be the consequence of an obvious lesion, or on the other hand it may be unassociated with any discoverable nervous or systemic disorder. The condition may give rise to nothing worse than an endurable dizziness on standing, or, by contrast, to a state in which the patient hurries from chair to chair in a crouching position to avoid fainting.[1] The excessive fall in blood-pressure when the upright posture is assumed is due to failure of the normal compensatory vasoconstrictor reflexes. In mild cases some patients complain of tachycardia, besides giddiness, on standing, but others do not have the tachycardia, which clearly compensates partly for the fall in blood-pressure. The condition may progress no further, or its severity may increase insidiously and other disabilities appear. The disorder is always worse in the heat, when the vascular bed is normally enlarged owing to cutaneous vasodilatation. Sweat production may fail, though the specialised axillary glands may be spared, difficulties in micturition and defæcation may develop, there may be diarrhœa or constipation, some patients complain that mastication causes pain and swelling in the parotid gland, and commonly erection becomes impossible.[2-4] All these disturbances are clearly related to activity of the autonomic nervous system. The common complaints are due to sympathetic dysfunction, but the parasympathetic system may also be involved, and the manifestations must depend on the degree of involvement of one or both parts of the autonomic nervous system. Examination of the patient with orthostatic hypotension of autonomic origin usually reveals no abnormality of the somatic or central nervous systems, and no concurrent disease such as adrenal cortical hypofunction. In many cases the patients present in middle or old age with a history of some disability, weakness, and fatigue for a considerable time. On the other hand, the disease may manifest itself after some stress such as pregnancy[1] or spinal anæsthesia.[4] In one young man the onset apparently took place during an undiagnosed illness in which faint generalised erythema had been present.[3] There seem to be no pathological reports on patients who had the disease.

With the patient recumbent the blood-pressure is usually in the normal range; only when he sits or stands does his abnormality become obvious. Experiment supports the guess that the sympathetic (and parasympathetic) nerves are at fault. In health, blood and urinary adrenaline and noradrenaline increases with a change from the horizontal to the vertical position, either actively or passively by tilting.[5] This is a quantitatively measurable sign of increased activity of the sympathetic nerves, which release noradrenaline at their vasomotor endings and adrenaline from the adrenal medulla. In patients with postural hypotension there is little or no increase in the blood and urinary concentration of these catechol amines[5]—a clear indication of failure somewhere in the chain of events leading to necessary vasoconstriction. A similar absence of rise in noradrenaline concentration is found after sympathectomy.[6] Parasympathetic involvement is demonstrated by failure of hypoglycæmia to increase gastric acidity, absence of change in pulse-rate on administration of atropine, and absence of bradycardia in response to administered adrenaline[4], massage or compression of a carotid sinus evokes no change in pulse-rate or blood-pressure when the parasympathetic inhibitory nerves to the heart are functionless.[4] These are not the only demonstrable signs of autonomic imperfection. Withdrawal of blood or the administration of an intravenous infusion leads to an exaggerated fall or rise of blood-pressure owing to the failure of reflex mechanisms which normally and rapidly damp the effect of volume change by constriction or dilatation of visceral, muscular, and cutaneous vessels.[3] Another sign of functional sympathectomy is hypersensitivity to pressor agents: thus an excessive rise in blood-pressure follows injection of a small dose of adrenaline, and as little as 10–20 milliunits of vasopressin as a single injection, or an infusion of 1 milliunit per minute, may induce a rise in blood-pressure.[3] Normal people show little pressure change after far larger doses of vasopressin,[7] even when these are great enough to produce visible paling of the skin, but after administration of a ganglion-blocking agent normal people respond like patients with postural hypotension.[4] (In a young patient whose renal function was examined, the response to an infusion of normal saline solution resembled somewhat that of many four-footed animals whose vasoconstrictor system is less sensitive than that of man with his upright posture. The patient responded with a rapid urine flow, a high rate of loss of sodium, and an increase in glomerular filtration-rate.[3] Normal people maintain a steady glomerular filtration-rate even after such an infusion, and lose the excess water and sodium far more slowly.)

Some of the various suggested causes of this disorder—for instance, inadequate return of venous blood to the heart,[8] and an abnormally great reduction of blood-volume on standing[9]—are probably in fact consequences of autonomic dysfunction. Where sympathetic activity is low or absent the arterioles and capillaries will lack tone, blood will pool easily, and the capillary walls will be more than usually permeable to plasma A lesion giving rise to these effects could lie at one or more of several sites In their article last week Professor SHARPEY-SCHAFER and Dr TAYLOR[10] reported instances of orthostatic hypotension in patients with diabetic neuritis and showed that in this condition, even when it is severe, absence of circulatory reflexes was by no means inevitable But where the reflexes were absent the efferent vasomotor pathway was intact, as was shown by normal vasodilatation to indirect heating, and normal constriction of finger vessels on taking a deep breath These workers conclude that in diabetic neuritis, as in tabes, the lesion lies on the afferent side of the reflex arc But in the instances of "pure" or "simple" orthostatic hypotension which have been discussed here it is not clear where the lesion lies, nor what it is In some cases, as in diabetic neuritis, apparently normal vasomotor responses can be elicited by pinching the skin—an indication that the peripheral part of the vasoconstrictor nerves is intact[11] In other cases a normal response can be obtained in the upper but not in the lower limbs[11] The only explanation is that painful stimuli may share a final common path with the postural reflexes, but must take a different route somewhere On the other hand, the fact that the disorder can be progressive and ultimately affect both parts of the autonomic system points to some central lesion

Since we are ignorant of the origin and pathology of this disease, treatment has to be symptomatic The mildest cases may be much helped by elastic stockings and body-belts In the more severe cases, without such mechanical aids the patient may faint on standing If he falls flat, perhaps not much harm will be done, but if he falls in such a way or place that he is not flat, then he may die of cerebral anoxia before help comes Theoretically any agent which raises the blood-pressure may be useful, for the simple reason that when the patient stands, although the proportional fall of blood-pressure may be as great as before, the lowest level is above that which leads to cerebral anæmia In this way the most disabling feature of the disease is moderated, but the disease is not cured, as is evident from the persistence of other symptoms such as hypohidrosis and failure of erections[2-4] With vasoconstrictors the difficulty is to find one with a long action which does not induce tolerance or have undesirable side-effects With the adrenaline-noradrenaline type of drug the benefits are on the whole short-lived or produce, among other things, harmful local reactions due to the very vasoconstrictor effects for which they are administered[1] Another approach is to raise the blood-pressure by increasing the blood-volume, and success has been reported from administration of deoxycortone acetate in oil with extra sodium chloride in the diet[1] (Clearly any patient receiving a combination of deoxycortone acetate and salt must be under regular supervision) Recently 9-α-fluorohydrocortisone in doses considerably below those affecting the carbohydrate-regulating system has been found beneficial[2] One great advantage of this substance is that it can be given by mouth But, as with all other treatments, the basic defect remains, for when the patient stands the plasma-noradrenaline does not rise as it should

[10] Sharpey-Schafer, E P , Taylor, P J *Lancet*, March 12, 1960, p 559

Favism

FAVISM, "a singular disease chiefly affecting the red blood-cells", has been known for centuries since affected persons lived originally in the Mediterranean basin In modern times it has been most prevalent among the inhabitants of the island of Sardinia, with lesser groups in Sicily and Southern Italy[1], but in the past twenty years cases in other areas have come to light The disease is due to sensitivity to the ingestion of the broad bean (*Vicia faba*) or to inhalation of the pollen FERMI,[2] who recorded 1211 cases of the disease in 1905, found that 38% of the attacks were due to inhalation and 62% to ingestion LUISADA[1] pointed out that intake of a single seed can cause the syndrome, and attacks have been brought on by drinking water in which fava leaves have been kept or by drinking milk from a goat that has been fed on broad-bean plants The syndrome is the same whether brought on by inhaling pollen or by eating beans, but the pollen produces an attack within seconds whereas some hours elapse after eating beans before symptoms appear The first symptoms are dizziness, headache, nausea and vomiting, lumbar pain, and pyrexia, but in five to thirty hours the characteristic hæmoglobinuria and jaundice appear The urine varies from red to black, the jaundice is intense, and sooner or later pallor due to increasing anæmia appears The hæmoglobinuria and fever usually clear up by the fifth or sixth day, the jaundice persists somewhat longer, and the anæmia, if untreated, may still be present up to a month later The attacks are rarely fatal except in children, in whom the mortality may reach 8% Blood examination shows reduction of red cells to between one and two million per c mm , there is pronounced leucocytosis, reticulocytes rise to as much as 30–60%, and in fact the picture is that of acute hæmolytic anæmia The red-cell fragility is usually normal, the Donath-Landsteiner reaction is negative, and the Coombs antiglobulin test has been found to be negative

Cases of favism have now been reported from other parts of the Mediterranean littoral and from countries to which Mediterranean inhabitants have migrated MANSOOR[3] reported 2 cases from a single village in Israel A case was reported in the U S A by MCCRAE and ULLERY[4] in 1933, and there have been others since MCCARTHY[5] described a case in a 9-year-old boy admitted to hospital in Chichester, the boy's parents were of English descent as far as was known DISCOMBE and MESTITZ[6] described a case of favism after a meal of broad beans in an English-born child whose parents' families both came from Baghdad DISCOMBE and MESTITZ pointed out that the so-called "Baghdad spring anæmia", said to be due to the inhalation of the pollen of spring flowers, is very similar to favism Other plants now known to cause a similar syndrome include the stinkwood, the bog-bilberry or whortle-berry, a mushroom (*Morchella esculenta*), male fern, and a pea (*Pisum sativum*).

[5] McCarthy, O R *Lancet*, 1955, i, 749

Favism, and presumably the similar syndromes, is regarded as of allergic origin, and the protein of *Vicia faba* has been clearly shown to provoke an attack of hæmolysis with accompanying hæmoglobinuria and jaundice in a sensitive patient. But we have only recently learnt what the abnormality in the red cells is that makes the patient sensitive to these proteins. In January we drew attention to a new familial abnormality of red blood-cells[7], in this condition the red cells are deficient in the enzyme, glucose-6-phosphate dehydrogenase, and this deficiency appears to be the basis of some unusual drug-sensitivities causing hæmolysis. The defective red cells can be recognised by a test devised by Beutler et al.[8] The red cells are suspended in a heparin-containing phosphate buffer of pH 7·6 to which has been added glucose 200 mg per 100 ml of the reducing-substance, acetylphenylhydrazine, 100 mg per 100 ml, the mixture is incubated for four hours, and wet preparations are then made and stained with cresyl-violet. In a sensitive person five or more Heinz-bodies appear in more than 40% of the red cells. Another method is to demonstrate the inability of the abnormal red cells to retain glutathione in the presence of reducing agents.

This enzyme abnormality of red cells has been demonstrated in cases of favism by workers in Italy and Israel.[7] In this issue Dr Gower and Dr Frommer describe a case, seen in London, of a 3-year-old Cypriot child with the typical hæmoglobinuria and icterus. On the first admission the cause of the syndrome was not detected, but when, eight months later, he was readmitted with the same syndrome, a history of eating broad beans was obtained. The child recovered rapidly without needing blood-transfusion, and later, when his red cells were investigated by the Beutler Heinz-body test, 80% of his cells developed multiple Heinz-bodies. A modern twist to this story is given by the fact that the attack occurred in the month of March. In Sardinia the disease is strictly seasonal, the inhalation cases occur in April and May when the *Vicia faba* plants blossom, and the ingestion cases occur between May and August when the beans are fresh. But in London broad beans can be bought out of the deep-freeze and so favism may develop at any time of the year.

This case in a Cypriot immigrant and occasionally in others in Great Britain should remind us to include favism in the differential diagnosis of unexplained attacks of hæmolysis and hæmoglobinuria. We now have a test for detecting the abnormal red cells, and need not go to the length of precipitating an attack with a test dose of broad beans. And since favism and similar syndromes are so easily avoided, the diagnosis should be made whenever possible. Favism is well known to be a familial abnormality, so tests among the patient's family are often rewarding.

MATERNITY-HOSPITAL REPORTS

For many years it has been the custom in this country and in the Commonwealth for leading maternity hospitals to produce an annual account of their work, but rising printing costs and changes in obstetric practice make it necessary to review the form and value of these reports. In the first quarter of this century they followed the example set by Dr Charles Longridge, of Queen Charlotte's Maternity Hospital, London. In 1928 the obstetric section of the Royal Society of Medicine suggested a standard plan, which was widely used until the Royal College of Obstetricians and Gynæcologists, in 1948, recommended a number of changes. Two years ago the college, in the interest of economy, suggested that hospitals should continue to draw up the standard report, but for general distribution should prepare a brief statistical summary. Few hospitals so far have put this recommendation into practice, but it seems likely that in time most will do so.

A certain amount of variation and experiment is evident in recent reports. The last three from the Simpson Memorial Maternity Pavilion, Edinburgh, have been largely in summarised form, and, like that from the Mill Road Maternity Hospital in Liverpool, have been favourably received. In an attempt to stimulate standardisation the Edinburgh reports now have an appendix with a comprehensive list of definitions. G T D Barr, in his brief statistical analysis of the work of the Princess Mary Maternity Hospital, Newcastle upon Tyne, in 1957, has included a critical review by Dr William Walker of the hospital's experience of rhesus immunisation between the years 1948 and 1958. This hospital, in its annual reports, intends to produce from time to time an account of the hospital's management of some obstetric or pædiatric problem.

The Rotunda, the Coombe, and the National hospitals in Dublin continue to produce detailed yearly reports, and for several years these have been discussed at special meetings of the Royal Academy of Medicine in Ireland. Last year Prof R J Kellar, as guest speaker, on the whole welcomed such reports, provided they were properly prepared, and he thought that they served a useful purpose.[1] Some obstetricians would question this view. In former years they drew attention to the considerable maternal mortality and morbidity associated with childbirth, but this need has largely passed, and today there are more effective and less expensive means of studying maternal deaths.[2]

Whether these reports can contribute to our knowledge and understanding of perinatal mortality is arguable. Generally the information contained in them lacks the clinical and pathological precision required for serious study, and, owing to differences in methods of recording, one report cannot readily be compared with another. Most hospital populations are heavily selected, and the true incidence of the various complications which may threaten the life of the child cannot be established. A comparison of hospital reports will never explain why, in this country, perinatal mortality is higher in the North than in the South and in industrial than in rural areas. Before we can understand the social and medical factors which together are responsible for these differences we must define and compare total communities This was hinted at in the Cranbrook Committee's report[3] when a plea was made to extend hospital clinical reports, with the help of the local authority, to cover the domiciliary midwifery service in the area

[2] Report on Confidential Enquiries into Maternal Deaths in England and Wales 1952–1954 H.M Stationery Office, 1957

In defence of annual clinical reports it may be said that collection and presentation of the material is good training for registrars and housemen But the filling in of a standard form by junior medical staff must not be mistaken for a dependable records system Much more is required The consultants must set the standard and be prepared to supervise the quality of case-note taking, and themselves take part in transcribing medical information from the case-notes into the records system Definitions must be discussed and agreed on The success of any records system depends primarily on the quality of the information fed into it To match this effort on the part of experienced medical staff, there must be an efficiently organised records department

The prestige value of annual maternity reports should not be allowed to weigh too heavily The time is opportune for administrative officers, as well as obstetricians, to look carefully at this matter and to decide whether reports in their present form justify the expenditure Of the various alternatives, a relatively simple regional maternity report has much to commend it

INDIAN TUBERCLE BACILLI

THE response to infection by tubercle bacilli differs between races Such differences are found in mixed communities—for example, the Malays and Chinese in Singapore and the white and Negro races of the United States—so it seems likely that the major factor is in the hosts and not in the bacilli But some clinicians have thought that in addition the virulence of strains of tubercle bacilli may differ in different parts of the world, the idea was apparently based on alleged differences between the disease in Europeans infected in the East and the disease in those infected in their own countries There has been little bacteriological support for these speculations Although strains of tubercle bacilli have long been known to differ in their virulence for laboratory animals, there was no acceptable evidence that the pattern of virulence among the strains differed in one country from that in another In India there was a suggestion that a proportion of the strains isolated from patients were less virulent for guineapigs than European strains[4–6], but accurate estimation and comparison is difficult, requiring careful design and execution of the experiments A cooperative investigation has now firmly established differences of virulence between strains obtained from patients in Great Britain and in South India[7]

83 South Indian and 29 British strains of *Mycobacterium tuberculosis* were studied in two laboratories in Britain and one in Madras All were sensitive to streptomycin and isoniazid About three-quarters were tested by the niacin test, and all were shown to be of human type Three strains of guineapig were used—one bred in London, one in Madras, and the third in both places Virulence was assessed by the amount of disease found in the animals six and twelve weeks after infection, the amount being expressed by an arbitrarily defined method of scoring The best measurement of virulence was found to be the "mean index"—the score divided by the survival-time of the animals The Indian cultures were found to have a wider range of virulence than the British, and only about 30% of them were as virulent The least virulent of the Indian strains caused little more than local lesions In one experiment, using guineapigs bred for several years in Madras, the "mean index" from 24 Indian strains was 0 68 and from 11 British strains 1 64, in another, using guineapigs bred in London, the "mean index" from 8 Indian strains was 0 48 and from 6 British strains 1 23 Full analysis of the whole series of experiments showed that the findings had "with little doubt" been uninfluenced by the breed of animal, differences of diet, or technical errors The authors wisely emphasise that their results apply only to strains isolated from poor patients living in Madras city, and that there is no evidence that the Madras strains are less *infective* than British strains, although many of them are less *virulent* in the guineapig They point to the paradox that in India, although there is apparently more human tuberculosis than in Britain, it is caused by bacilli of lesser virulence to animals, and they suggest a reasonable hypothesis

Tubercle bacilli are mainly spread by patients with chronic cavitating disease The level of virulence that is of the greatest survival value to the bacilli is, therefore, the one that most commonly causes this type of disease In a country such as Britain, where the risk of infection is falling and the people are well nourished, attenuated strains may be unable to establish sufficient chronic cavitating tuberculosis to survive, and in these circumstances, high virulence has the greatest survival value On the other hand, where risk of infection remains high and the people are ill-nourished, as in the particular population studied in Madras, attenuated strains may more often be able to cause chronic cavitating disease and continue to exist "Attenuation may therefore be a modification imposed on the bacilli by the need to establish the correct balance between the susceptibility of the host and the virulence of the parasite"

BELL'S PALSY

WHEN a peripheral nerve rapidly becomes blocked and ceases to conduct, the neurologist's first thought is that the nerve has been compressed or stretched in some way, and this may of course involve some interference with the blood-supply to the nerve The facial nerve traverses a bony canal and is supplied by very small arteries, one of which is a branch of the external carotid artery and enters the stylomastoid foramen to supply the nerve It is not surprising therefore that many have considered that in Bell's palsy the facial nerve must either be compressed by œdema in the facial canal or else have its blood-supply interfered with, or that perhaps it suffers from a combination of both processes In any event it is reasonable to try the effect of therapy which will counter such processes

Korkis[1] reports remarkable success from stellate-ganglion blocks with 1% procaine solution, repeated, if necessary, every three days such blocks were applied one to four times, the average being two Of 20 patients with complete paralysis, 16 recovered completely within three weeks the 1 patient who did not recover fully was not treated until twenty-three days after the onset The results in cases of incomplete facial paralysis were very striking in that improvement was almost immediate Latterly Korkis has combined stellate-ganglion block with administration of prednisone

Any such measures are of course most likely to succeed if they are applied soon after the onset, and in this series treatment was usually started within a day or two after signs appeared

These results are so good that the method should be tested by others It is difficult to see how it can do any harm, and some serious disfigurements may be avoided

RADIOGRAPHIC DETECTION OF PRIMARY PEPTIC ULCER

THE mere exhibition of a dose of barium sulphate and exposure of radiographs is, it seems, commonly expected to decide whether a dyspeptic patient has a peptic ulcer This belief is implicit in case-reports which read " barium-meal examination showed ", as though the examination was self-controlled and at its conclusion the X-ray screening-couch presented an appropriately labelled ticket Certainly the demonstration of a peptic ulcer can be one of the simplest exercises in radiology, but quite often it is one of the most difficult

The radiological diagnosis of any lesion depends on two factors—demonstration and recognition The ease with which an ulcer is demonstrated depends on its size, its site, and the presence of any obscuring associated or unassociated lesion If an ulcer is less than 2 mm in diameter it is unlikely to be demonstrated even when it is in one of the sites where ulcers are most readily detected—namely, the middle third of the lesser curvature of the stomach and centrally on the anterior or posterior wall of the duodenal cap Much larger lesions involving only superficial erosion of the mucosa cannot be shown radiologically Few organs have a wider range of shape, size, and situation than the normal stomach Various degrees of rotation on both longitudinal and transverse axes are encountered, and in some cases the word " axis " has no real meaning since the rotation is so bizarre Detection of an ulcer on the upper part of the posterior wall of a stomach of this kind may be extremely difficult Normal rugal pattern seen in profile can simulate ulceration, outpouchings of mucosa in the cascade type of stomach are deceptive, and small gastric diverticula, though less confusing, may give rise to trouble in interpretation Ulcers in the roof of the antrum have an unfortunate knack of trapping fluid when the patient is erect, and unless carefully sought with the patient prone they may be missed even when they are of considerable size. Juxtapyloric gastric ulcers may be obscured by spasm or fibrotic contraction of the antrum Ulcers on the middle third of the lesser curvature are usually easier to detect, but even here confusing and fallacious appearances of deep ulceration may be found[1, 2] when the actual lesion is no more than a superficial erosion A gastric ulcer in a large hiatus hernia (which may contain stomach, duodenal cap, and perhaps part of the colon as well) may be almost impossible to demonstrate, on account of gastric volvulus When the stomach is already scarred and deformed by old-standing ulceration, the detection of present ulceration may be especially difficult

The distinction of simple from malignant ulceration in the stomach is at times impossible if the surgeon and morbid anatomist with the affected tissue between their fingers can sometimes only guess, the radiologist is hardly to be blamed for some errors Nevertheless, when the experienced radiologist confidently diagnoses a simple ulcer, he is seldom wrong[3] The mere size of the ulcer crater is not a reliable guide Robbins,[4] in a consecutive necropsy series of 190 benign and 68 malignant ulcers, found that of those with a crater diameter of more than 4 cm 20 were simple and 33 malignant, this is unlikely to indicate the full incidence of large simple ulcers since such cases are often treated satisfactorily and do not appear at necropsy Large size is an embarrassment to the radiologist since he cannot easily apply the criterion of ulcer projection from the gastric outline (probably the most accurate indication of simplicity) to an ulcer which has destroyed more than a quarter or a third of the gastric contour from which its projection is to be judged Carman's[5] meniscus sign can certainly be found in simple ulceration Location of the ulcer in the antrum or on the greater curvature, though increasing the likelihood of neoplasia, is no positive indication of this

Duodenal ulceration is much more often obscured by accompanying scar deformity than is gastric ulceration In many patients the first and second parts of the duodenum cannot be kept under the same continuous controlled observation as can parts of the stomach The duodenal contents may be propelled rapidly and the duodenal cap may remain empty—the terms " irritable " and " spasm " are probably a measure of the radiologist's frustration as well as of the behaviour of the duodenal cap Considerable ingenuity and practice may be needed to satisfy the orthodox radiographic principle of obtaining at least two views at right-angles to each other of the part examined prone and supine views with and without compression and air contrast relief patterns[6] may be needed It may be even more difficult to establish the existence of an ulcer in a grossly deformed duodenal cap in a patient with a long history than to exclude the presence of an ulcer in a patient with a history of only a fortnight's dyspepsia Paterson and Hancock[7] have illustrated some of the difficulties in correlating the radiographic appearances of duodenal ulcer with the surgical findings shortly afterwards They note that ulcers may appear as polyp-like filling defects in the duodenal cap owing to the œdema around the crater preventing or almost preventing the crater being filled with barium In some patients the whole of the duodenal cap is replaced by an ulcer which appears so large and symmetrical that it may be mistaken for a normal duodenal cap[8, 9]

Postbulbar duodenal ulcers present difficulties of their own[10, 11] They arise as a rule in well-nourished hypersthenic men in whom the duodenal cap may be quite normal and when filled completely obscures the site of ulceration immediately beyond. These ulcers, missed by routine radiographic examination, may be undiscovered at laparotomy since they are usually in the medial and posterior wall of the upper part of the descending duodenum in a most inaccessible region for direct

surgical palpation, they often bleed, and they often are associated with severe back pain which in some instances has provoked exploration for non-existent lumbar disc lesions

Appearances mimicking simple duodenal ulceration are sometimes produced as the result of extrinsic involvement by tumours—notably from the pancreas and gall-bladder Mimicry may be exact, since duodenal ulceration of a sort is present and the deformity due to fibrotic contraction round a simple ulcer is counterfeited by infiltration and contraction due to neoplastic involvement

Rarely, simple peptic ulceration is found in the distal duodenum or jejunum [12–14] Here the ulcer crater may be obscured by associated " duodenitis " or " jejunitis "

What, then, is the place of radiology in the diagnosis of peptic ulcer? It is certainly not an exclusory method of examination A barium-meal examination is undertaken to show an ulcer, and if one is demonstrated its existence is proved, but the ulcer may be there even when careful search has failed to reveal it The advantages of the radiological investigation lie in its scope—the opportunity to demonstrate independent but not necessarily irrelevant lesions such as gallstones, hiatus hernia, pancreatic tumours, small-intestine disease, and even supradiaphragmatic abnormalities In competent hands accuracy of diagnosis is great, but just how great it is impossible to say under the conditions of clinical practice The detection of a lesion is easier than its diagnosis in terms of histology Occasionally radiological interpretation is correct even when the gastroscopic and surgical findings have run counter to it Periodic radiological observation of, say, a gastric ulcer may indicate that continued medical treatment is unlikely to achieve more than palliation [15, 16] Certainly the radiologist who plays a lone hand without close support by clinician and pathologist will make many mistakes, but equally certainly as a member of a team his honest endeavour will provide a full share of aid in the elucidation and treatment of one of the commonest ills to which modern flesh is subject

HISTORY AND THE PARASTERNAL LYMPH-GLANDS

" Dr W H Cushing, my house surgeon, has in three instances cleaned out the anterior mediastinum on one side for recurrent cancer It is likely, I think, that we shall in the near future remove the mediastinal contents at some of our primary operations " This could almost have been put to a medical panel in a radio transatlantic quiz of the type which is now becoming popular at some scientific meetings and shame on the doctor, American or British, unable to identify the author as Halsted [17] The question-master would probe further before awarding three marks The topic? Breast cancer—one more mark The point of specific interest? That here is the first known record of interest in the spread to the internal mammary lymph-glands of cancer from the breast The next quotation to be identified by the panel might well be " The following cases, the notes of which have been prepared by my registrar, Mr D H Patey, illustrate the control of sternal recurrence in breast cancer, sometimes for years, by buried radium treatment, with relief of pain, disappearance of the swelling, and healing of the ulceration if present " And shame to the British side at least if they could not recognise the voice of Sampson Handley [18] Handley had stimulated Stibbe to undertake anatomical dissections which revealed lymph-nodes at a plane anterior to the internal mammary artery opposite the upper three and the sixth intercostal spaces [19]—work which has been substantially confirmed by Urban,[20] whose researches reveal only a slight variation in incidence in comparison with the figures given by Stibbe Handley the elder acted on this anatomical knowledge and placed his radium needles in the appropriate spaces His son,[21] carrying researches further, showed that almost a third of 139 patients with " operable " breast cancer had invasion of the internal mammary chain, involvement being three times greater in medially than laterally placed growths, internal mammary metastases were present in over two-thirds of growths situated medially in the breast

These findings have posed a therapeutic problem which some have attempted to solve surgically [20] [22] (Wangensteen [23] fulfilling the hopes which Halsted voiced for his own technique [17]) and others radiotherapeutically It has proved difficult to deliver an adequate dose of X-irradiation in the area without damaging structures in close proximity [21], but Smithers and Rigby-Jones [24] have now developed a technique which permits irradiation of the internal mammary nodes (or parasternal in their nomenclature) of patients with cancer in the medial half of the breast and of those with laterally placed lesions in whom the axillary glands are involved Lest it should be thought that attention paid to this area when so wide a lymphatic field is at risk savours of straining at a gnat, it is worth recording that one of Sampson Handley's patients submitted to radical mastectomy in 1923 at the age of 37 developed a recurrence in the second parasternal space which he treated with a radium implant This was the first patient he treated thus, and she survives today, 37 years later, without further recurrence

A KNIGHTHOOD in the Royal Victorian Order has been conferred on Mr J H PEEL, who attended the Queen in her recent confinement Mr Peel is obstetric and gynæcological surgeon to King's College Hospital, director of clinical studies in the medical school, and a councillor of the Royal College of Obstetricians and Gynæcologists To the many who know him in these and other capacities this honour will give particular pleasure

Dr VERNON HALL, who attended as anæsthetist, is appointed C V O He joined the staff of King's College Hospital in 1931 and has been dean of the medical school since 1951

INDEX TO THE LANCET

THE index and title-page to vol II, 1959, which was completed with the issue of December 26, is enclosed with each copy of our present issue This practice will be followed with future indexes, and accordingly those who wish to receive the index need no longer apply to our office

Points of View

SOME UNCRITICISED ASSUMPTIONS IN PSYCHIATRIC THOUGHT

N. McCONAGHY
M.B., B.Sc. Queensland, D.P.M.
SENIOR LECTURER IN THE UNIVERSITY OF MELBOURNE
From the Department of Psychiatry,
Royal Melbourne Hospital and Prince Henry Hospital

IN current psychiatric thinking a number of unjustified assumptions are in constant use. As there is a growing tendency to train medical students and practitioners in psychiatric therapy—often very uncritically—an examination of some of these assumptions may be of value.

HOMŒOSTASIS

The concept of homœostasis is used in psychiatric theory in an unscientific way. Unfortunately, like so many other concepts in psychiatric theory, it has been borrowed from another science—in this case physiology. There it was introduced to describe mechanisms whose interactions maintain the constancy of certain physiological states—e.g., the respiratory mechanism, which maintains the tissue levels of oxygen and carbon-dioxide. It was realised that, for the cell to remain alive, its environment must be kept relatively constant, and that there must be many mechanisms serving this purpose.

Imagine, however, the harm that would have been done in physiology if no attempt had been made to uncover the complex interplay of reflexes and central nervous responses which explains the working of these mechanisms. Much painstaking laboratory work could have been saved by ascribing the activity of each of these mechanisms to an inherent homœostatic drive which came into play when any equilibrium was disturbed and returned it to normal. Thus, without any knowledge of the Hering-Breuer reflexes, the carotid body, and the respiratory centre, respiration could be attributed to the oxygen-seeking drive, or perhaps, for the more sophisticated physiologist, by the interaction of the oxygen-seeking and carbon-dioxide-avoidance drives.

Yet this apparently ludicrous state of affairs has been accepted widely in theories of behaviour. Just as it is obvious from the facts of cell life that homœostatic physiological mechanisms must exist, so for animal life to continue there must be similar behavioural mechanisms. For example, enough food and water must be regularly obtained, destructive stimuli avoided, sexual activity carried out, and young animals cared for. Hence a ready-made theory is available. Without further investigation of the mechanisms in the body which produce these activities, all this behaviour can be put down to a multiplicity of "homœostatic drives", such as a hunger, a sexual, a maternal, and a pain-avoidance drive. Any other drive can be added as behaviour is observed which cannot be explained by those already in existence—such as the notorious exploratory drive, hastily invented when it was shown that rats learned the layout of a maze without being supplied with food, water, or any other incentive covered by a known drive. The valuable research which might have uncovered the physiological basis of this behaviour has been neglected, and instead the relative strength of these postulated drives has been measured and ad-hoc equations have been devised to fit the measurements.

This concept is also used in psychoanalytic theory as an explanation of behaviour which can be formally considered as tending to an equilibrium.

> "The assumption has been made in various forms by many biologists that there is a basic vital tendency [sic] to abolish tensions that have been brought about by external stimulation and to return to the energy state that was effective before the stimulation. The most fruitful conception in this respect is Cannon's formulation of the principle of 'homeostasis'. It was the same basic principle . . . for which Freud, following Barbara Low, often used the expression 'Nirvana principle'. Homeostasis is, as a principle, at the root of all instinctual behaviour" (Fenichel 1946).

If psychiatry is going to borrow concepts from other sources, they must be used with the same accuracy. We know that homœostatic mechanisms must exist in behaviour, but we should study them to learn how they work, instead of using them to explain what they merely describe.

WE ALL HAVE DYNAMICS

The assumption that psychiatric illnesses can be explained in terms of "personality dynamics" is so well established that psychiatrists who find the knowledge of dynamics unhelpful in understanding and treating illness (the so-called organic psychiatrists) often reject the existence of dynamics in the healthy personality and in some personality deviations, or else use them with reluctance and embarrassment (Mayer-Gross, Slater, and Roth 1954). But surely it is the dynamic psychiatrist who should be embarrassed. Imagine the reaction of a physician to the following dilemma.

He is told that his patient has just become ill, he is given the symptoms and a list of investigations of physiological mechanisms, but he finds there is no essential difference between the results of the investigations and similar ones on people without symptoms. Does he consider the possibility that these mechanisms are not responsible for the illness, that perhaps a new and as yet uninvestigated factor has caused the illness? No, he wastes no time with this easy and obvious solution: a new and revolutionary insight has come to him. All the people are sick, but only some have actually developed symptoms.

The dynamic psychiatrist seems to reach this position without recognising its illogicality. Having set out to treat the psychiatrically ill, he decides to investigate the processes in the sick and the healthy, showing in fact a preference for the healthy. This happened early in the development of dynamic therapy.

Freud's first book *Interpretation of Dreams* was not based on the study of symptoms—indeed not even on the study of patients. "I do not propose to make use of . . . the dreams of neuropaths, from which no valid inference could be made as to the dreams of normal people" (Freud 1953).

Next, when the dynamic psychiatrist discovered among the people without symptoms of illness a new group with a certain type of behaviour, he labelled the processes to which he attributed their behaviour as "neurotic". This term showed not only that he assumed them to be pathological but also pathological in the same way as the processes in patients with neurotic symptoms.

> "thus the essence of normality is flexibility, in contrast to the freezing of behaviour into patterns of unalterability which characterise every manifestation of the neurotic process" (Kubie 1959).

This use of "neurotic" to cover two groups of people—those with symptoms of neurosis and those with a specific type of behaviour—is surely one of the most confusing assumptions of psychiatric thought. Admittedly there are people whose emotional behaviour is repetitive and socially crippling we have all met people with a long history of inability to accept instructions from people in authority, others who so need to be reassured of our regard that they test it by making greater and greater demands until they destroy it, and others whose behaviour varies consistently between complaisance and aggression But is there any evidence that these people whom we all now describe as "neurotic" have any more symptoms of neurosis than the average "non-neurotic" (in this behavioural sense) members of society? At least we should stop to consider what relation, if any, exists between these people and those who have symptoms of one of the known psychiatric illnesses? The assumption of such a relation should not be allowed to go unquestioned merely because it has been masked by a change in definition

Once he had attributed the behaviour in this group to a pathological—a "neurotic"—process, the dynamic psychiatrist went on to regard the processes in the healthy as pathological too For the difference between the neurotic (as defined above) and the rest of us is only one of degree we all have some need to reassure ourselves about other people's friendships and so on By definition, however, it is not certain extreme forms of behaviour but the dynamics which produce them which are neurotic and so pathological Hence we all have pathological dynamics as Kubie (1959) puts it, "a neurotic process evolves in some degree in everyone" Note he does not say that the same dynamic processes which we see in the neurotic are present to some degree in everyone The processes themselves are termed neurotic

Superficially, organic psychiatry shows a similar tendency to treat some normal people as having underlying pathological processes—e g , in the concept of the *formes frustes* But there is a fundamental distinction Let us take the obsessional personality as an example

The organic psychiatrist would consider this a normal personality with valuable as well as harmful qualities But, from the psychoanalytical viewpoint, the behavioural patterns of the obsessional personality are thought really to be concerned with fæces, to act as a defence against the emergence of pathological behaviour, and to indicate fixation at an anal level of development The implication of pathology and of a somewhat crippled personality is unavoidable Even the term "well-adjusted", often used of the approved personality, bears the clear implication there is something to adjust to

Since the dynamic therapist sees the processes shared by the normal and the ill as pathological, it follows that he sees everyone as ill So he abandons the definition of normal as "people without symptoms" Indeed Ernest Jones (1948) rejected the "statistically normal mind" and concluded that a "normal mind" in his sense does not exist

Once everyone is ill, the presence or absence of symptoms is unimportant, and the dynamic therapist has rejected symptom-relief as an index of therapeutic success In *Psychopathology of Everyday Life* Freud described the apparently meaningless random acts which everyone carries out as "symptomatic acts", thus making (and masking) the fundamental assumption that they are comparable with psychoneurotic symptoms Once aspects of normal behaviour—initially errors and dreams but later patterns of emotional behaviour—are treated as identical with symptoms, symptoms themselves can have no significance

This lack of interest in symptoms is only part of a general attitude towards all overt behaviour As the dynamic therapist is concerned only with the processes within the patient, what actually happens to the patient is of little importance This attitude explains why the dynamic therapist, having actually described the characteristics of overt behaviour in the neurotic, has made no effort to distinguish them from the normal To do so he would have to assess the degree to which this type of behaviour was present—that is, he would have to make a social judgment as to how the patient is managing his relationships with his friends, at his work, in his sexual activities, and so on The therapist, by virtue of his method of never seeking information, is unable to obtain this material, and in any case he does not regard statistical normality in these respects as evidence of mental health Often analysts seem to prefer, as patients, people without overt evidence of illness after all their dynamics are the same, and there are no troublesome symptoms to occupy the patient's attention and get in the way of therapy This is seen in the hospital or clinic where the analyst becomes more interested in the staff than in the patients

It would seem that really the dynamic psychiatrist has always been interested in the motivations of the normal, but has excused and masked this interest by adopting a new set of terms which enable him to see the normal as pathological and indeed as no different from the patient with a neurosis But in fact there are two continuums—the normal and the psychiatrically ill and the normal and the neurotic Though the distinction in both cases is one of degree, it is no less real than the distinction, say, between short and tall

Accepting that these two continuums exist, we could agree that the dynamics revealed in the normal and the neurotic often seem helpful in understanding the behaviour of these two groups Awareness of the dynamics may be useful in treating the neurotic, provided some sense of proportion is maintained about what behaviour actually justifies treatment But are they of value in the understanding and treatment of psychiatric illness? Often the dynamics revealed in the psychiatrically ill are just as apparent once the patient has recovered Again similar dynamics seem to be described in different psychiatric or even psychosomatic illnesses as well as in apparently healthy people thus guilt about the expression of hostility is recognised in anxiety states, obsessional neuroses, depression, migraine, and hypertension—not to mention its presence in many of the colleagues of the dynamically orientated Are these dynamics necessarily related to the illness or are they basic to the normal-neurotic continuum of personality present in everyone sick or well?

Possibly emotional factors are responsible for the onset of a psychiatric illness, but could they not be so in the manner that a lowering of resistance is responsible for the onset of an infection? Once the infective process has begun, its symptoms and treatment must be understood in terms of the attack of the specific organism on the body, not in terms of the processes causing the lowering of resistance Could not a disturbance of the patient's dynamics allow other factors to produce the illness? Another possibility is that the psychiatric illness, once present, will be used by the patient for his own emotional needs, thus producing an apparent dynamic reason for the illness

At least these possibilities should be considered, especially when there is growing evidence that the dynamic treatment of psychiatric illness has no more success than would be expected from spontaneous remission (Schmideberg 1958, Hastings 1958, Wallace and Whyte 1959). Certainly this evidence is not entirely convincing since the relief of symptoms is never used as a criterion for the success of dynamic therapy, no completely valid measurement of its value will ever be possible. But could not this be evidence of the analyst's recognition (dare we say unconscious?) that his therapy is suited to the readjustment of personality dynamics rather than the relief of symptoms. And in fact may not this be the rightful place for this treatment? People sometimes come to the psychiatrist, not with an illness, but with a personality they wish changed. The psychiatrist who is unsympathetic towards a dynamic approach may not be interested in such a patient. Surely if this person is really motivated to change, if he is prepared to be interested in the unravelling of his dynamics, and if he is verbally intelligent enough to understand the concepts that would be used, he may be helped by dynamic psychotherapy.

THE AGGRESSIVE *v* THE NON-DIRECTIVE PSYCHIATRIST

There is an increasing belief that general practitioners should be trained in dynamic psychotherapeutic methods, and courses have been started in some centres. But the propagation of psychiatric theory without sufficient awareness of its implicit assumptions has in the past proved harmful. For example, theories which laid stress on the damage done to the personality by incidents in childhood, without at the same time emphasising the creative positive role of environment, led to the idea that any influence might harm the child and hence to the concept of a completely "permissive" upbringing.

Now the danger exists that a potentially harmful form of treatment will become available to those who will be aware only of the damage that can be done by alternative methods of therapy. For many years the psychiatrist who uses physical methods has been reproached by his dynamically oriented colleague for expressing his own aggression in these methods. Again, "directive psychotherapy"—that is to say, actually giving the patient directions about how to manage his problems—is regarded as unrefined and brutal. The implication is that the dynamic method of treatment is infinitely more gentle. But let us examine this method, in its pure form.

The patient goes with an illness to his dynamically oriented doctor to find that at the end of his consultation, even though he may have specifically asked for this information, he has not been told what is the matter with him, how long he will be ill, what treatment (if any) he will receive, or even whether he will recover or not. However the doctor has listened carefully and given him another appointment. As the consultations grow in number and the patient asks more persistently for reassurance on these points, he is still denied it. Nevertheless the doctor shows a regard for the patient by continuing to grant regular and long interviews. The patient must surely feel extremely anxious and annoyed with his doctor for denying him what he is so used to expecting in the usual doctor-patient relationship. Yet he must also feel grateful to the doctor for the unique degree of interest shown.

Further evidence of this interest is the doctor's regular "interpretations" of the patient's behaviour. But the patient must also regard these interpretations as indicating behaviour on his part which falls short of the ideal, and which should be changed: that is to say, he must regard them as being both criticisms and directions. Many analysts seem to believe that in their interpretations they reveal the truth to the patient in a completely objective fashion. This may be so, but if the purpose of the treatment is to change the patient, the interpretation must be the most important means. And surely the patient is aware, or at least expects, that he is to be changed by treatment, and soon realises that the main treatment he receives is by the interpretations. Hence he must take them as indications to change and as criticisms that his present behaviour is less than ideal in these respects. And given the dynamic therapist's view that the healthy mind does not exist, there will be no shortage of areas where the patient's behaviour is not ideal.

Of course no matter how objective and valid the interpretations are, many must be felt by the patient as critical—e.g., when he is told he is seeking the love, sympathy, or approval of the doctor, or when he asks for treatment and is told he is seeking a magical solution to his problems. However, apart from this, I believe that interpretations which are not overtly critical and directive must be felt as such when given in the therapeutic situation—i.e., when the patient is expecting treatment which will change him.

So the patient must feel he is both denied reassurance and continually criticised, for he is always being told where his behaviour falls short of the ideal, without ever receiving any praise for his positive qualities. At the same time the therapist delivers these intellectual criticisms in a completely objective manner, without any sign of emotional disapproval, and in fact gives the patient signs of approval, albeit unemotional ones, in that he continues to give regular and long interviews in which he shows great interest in the patient. In short, in this situation the patient must, and does, develop ambivalent feelings of resentment and gratitude to the doctor—the "transference feelings". To make these feelings more certain and intense the interpretations are useful again. For whether the patient speaks of his love for his wife, his jealousy of his siblings, his need for the regard of his employer—indeed whatever he talks about—he is told he is really talking about his feelings to the doctor.

The patient is unable to express much of the resentment he feels in the interview. He is prevented partly by his feelings of gratitude and obligation, perhaps also of respect towards the doctor, but probably mainly because his resentment seems irrational and unfair in face of the doctor's apparent objectivity and lack of emotion. So the patient departs from the interview annoyed and takes out his anger on his workmates, relatives, or friends. The damage the patient can do in this way is accepted by the dynamic therapist, who calls it "acting out".

In brief, a situation is constructed in which the ill patient is held by feelings of obligation and hopes of recovery, and must tolerate not only a complete lack of reassurance but also continued intellectual criticism from a doctor towards whom he is encouraged to develop extreme ambivalent feelings. At the same time he is denied any help in dealing with his immediate problems, many of which may be due to the acting out of these feelings. This same doctor regards as overtly aggressive a colleague who tries to help the patient to deal with his symptoms and his problems. But is not the dynamic situation one of the most subtle and refined means of expressing passive aggression devised? May not this personality characteristic influence the psychiatrist in his choice of therapy, and does this tendency to passivity explain his choice of the word "non-directive" to describe this treatment. His apparent unawareness that the development of an intense emotional yet ambivalent relationship is a powerful manipulative process—possibly the most powerful known to man—seems otherwise inexplicable. It would show a clearer understanding of this technique if it were described as "non-supportive" rather than "non-directive".

Dynamic psychiatrists who work with schizophrenics seem to recognise that the technique is extremely traumatic to and demanding of the patient.

> "Abandon analysis of the positive transference, negative transference, of course, may come of itself, and must be overcome by explanation, psychoanalysis and the analyst's

behaviour The psychiatrist must preserve the positive transference by siding with the patient in any of his conflicts " (Federn 1953)

" Too much is expected from the psychiatric patient as a rule a degree of co-operation, insight, and will-power we would not demand from a physically ill patient, yet the psychiatric patient is (by definition) much more disturbed " (Schmideberg 1958)

What advantages has it to compensate for these disadvantages ? It is possibly the most satisfactory method of revealing dynamics

Obviously the patient's description of his own feelings and behavioural patterns cannot be accepted because of his lack of insight and resistance to accepting the truth about himself A relative or friend's description may also be biased Both lack sophistication in understanding and describing behavioural patterns Only by actually experiencing the emotional demands the patient will make of a person who is important to him and by actually seeing how he expressed his feelings of love and aggression, can a psychiatrist fully appreciate the dynamics of a patient's inter-personal relations

If we accept that " non-supportive " psychotherapy, though illuminating to the doctor, is disturbing to the patient, should we not choose carefully the type of patient with whom it should be employed ? Surely patients who come to the psychiatrist for the relief of an illness should not be denied the support and reassurance of the normal doctor-patient relationship ? The decision to deny the patient this support should be taken only when there is good evidence that the patient can tolerate this, is eager to have his dynamic patterns changed, and is able to understand the abstract verbal concepts which will be used by the psychiatrist to give him insight

STAPHYLOCOCCAL INFECTION IN NURSES

D M DAVIES
M R C P

SENIOR MEDICAL REGISTRAR, THE LONDON HOSPITAL, LONDON, E 1

IN recent years the serious and worsening problem of staphylococcal infection in hospital has had close attention But this has been directed mainly to cross-infection in surgical wards, epidemics among the newborn, and pneumonic superinfection in patients with influenza One important aspect has been comparatively neglected —namely, the high incidence of minor staphylococcal infections among nurses and the considerable amount of working time lost thereby

INVESTIGATION

In the twelve months ended last June at The London Hospital, a record was made of the number of staphylococcal infections occurring in nurses, the sites of these infections, and the time the nurses were off duty because of them In addition, in 100 cases the sensitivity of the infecting staphylococcus to four antibiotics was studied and compared with the findings in an equal number of inpatients and outpatients during part of the same period

RESULTS

Among approximately 725 nurses on duty at the main hospital there were 146 cases of staphylococcal infection This figure represented 16 4% of the total admissions to the nurses' sick-quarters (In the previous six years the proportion had averaged 18 2%) The working time lost by the affected nurses was 1249 days, an average of 8 5 days each

TABLE I—DISTRIBUTION OF LESIONS IN 146 CASES OF STAPHYLOCOCCAL INFECTION IN NURSES*

Site	Face	Nose	Ear	Eye	Neck	Axilla	Arm	Hand	Fingers	Trunk	Pubis, perineum, buttock	Thigh, leg	Foot, toes
Number	21	6	7	22	4	12	8	1	43	10	5	6	5
Totals	60					64				15		11	

* The total amounts to more than 146 because some nurses had lesions in more than one site at the same time

TABLE II—ANTIBIOTIC SENSITIVITIES OF STAPHYLOCOCCI ISOLATED FROM NURSES, INPATIENTS, AND OUTPATIENTS

—	Number	Percentage of staphylococci resistant to			
		Penicillin	Chloramphenicol	Tetracycline	Erythromycin
Outpatients	100	75	1	10	
Inpatients	100	88	4	50	
Nurses	100	98	4	35	1

All the infections were of skin or soft tissues (A case of staphylococcal pneumonia complicating influenza was excluded from the series) As table I shows, the commonest site of infection was the finger (29%), and 83% of all lesions were on the face, neck, axilla, or upper limb

When the sensitivity of the staphylococci was tested, almost all (98%) proved to be resistant to penicillin, about a third (33%) to tetracycline, just a few (4%) to chloramphenicol, and only 1 to erythromycin (this organism being sensitive to chloramphenicol, oleandomycin, and novobiocin) Table II shows (1) that penicillin-resistant strains were more often found in the nurses than in the comparable series of outpatients and inpatients, (2) that tetracycline-resistant strains were commoner in the nurses than in outpatients but not quite so common as in inpatients, and (3) that the proportion of chloramphenicol-resistant strains was small and equal in nurses and inpatients, and even smaller in outpatients (though the difference is probably not significant) Erythromycin sensitivity was tested in too few patients to allow useful comparison

DISCUSSION

In nurses staphylococcal infections have a nuisance value out of all proportion to their severity, for, even when a lesion is trivial, the nurse must be removed from contact with patients until it has healed completely In most other occupations (except food-handlers and certain pharmaceutical workers) less working time need be lost

The proportion of nurses staphylococci resistant to the four antibiotics mentioned roughly reflects the frequency with which these antibiotics are used at The London and most other British hospitals (In our nurses' sick-quarters antibiotics are used as little as possible, and chloramphenicol and erythromycin are reserved for very serious infections—fortunately rare—resistant to penicillin and tetracycline)

The distribution of the lesions suggests that the most important factor in infection is direct skin contact This raises the practical question whether repeated use of a hand scrubbing-brush during working hours may play a part in the high incidence of finger infections, and whether the incidence could be lowered by discontinuing the use of such brushes Though no definite conclusion of this kind can be drawn from the present investigation, it is obvious that staphylococcal infection in nurses deserves further study, particularly since many chronically understaffed hospitals cannot afford the loss of working time which it causes

I am grateful to Lord Evans and Mr J E Richardson for permission to publish this paper and to Dr H B May, director of the clinical laboratories, for helpful advice and for permission to quote the results of routine antibiotic sensitivity tests carried out by his staff

NEW HOSPITALS IN ULSTER

In the five years since 1954, capital expenditure on hospital and specialist services in Northern Ireland has amounted to £7 5*s* per head of population In the rest of the United Kingdom capital expenditure in the five years has been £1 14*s* in England, £2 16*s* in Scotland, and £2 6*s* in Wales The Northern Ireland Hospitals Authority has spent about £15 million on capital development since it took charge of the hospital services in 1948, and it is now spending about £3 million a year One reason why the Authority has had opportunities that have been and are the envy of regional boards and boards of governors elsewhere is that Northern Ireland had tremendous leeway to make up in hospital building, and excuses for economy and delay that could be made to sound reasonable in England, Scotland, and Wales in 1948 (and in 1960) were totally unconvincing in Ulster Moreover, labour and materials have been easier to find in Northern Ireland since the war than in many parts of the United Kingdom, and, given the money, the Hospitals Authority was able to avoid some of the frustrations of shortages and get on with several ambitious plans Thus the Authority is now in the fortunate position of being responsible (among many other new things) for the first completely new general hospital to be built in the United Kingdom since the war (the North West Hospital, at Altnagelvin, near Londonderry), the first mental hospital to be built in the United Kingdom since the war (the Gransha Hospital, also near Londonderry), and the first substantial institution to be built in Northern Ireland providing inpatient care and training for those suffering from incomplete or arrested development of the mind (the Special Care Service Hospital at Muckamore Abbey, near Antrim)

Altnagelvin

The North West Hospital stands on high ground a mile and a half from the centre of Londonderry, and most of the wards in the 150-feet high building have wide views to the south-east over the impressive country around the Pass of Glenshane Work began on the site in 1951 and the hospital came into use on Feb 1 this year Its cost is about £2,600,000

The main building, set in 50 acres, has twelve floors, including basement, in the ward wing, and eight floors in the treatment wing, the two wings forming an L. At present there are 394 beds, but at a later stage the L will be converted into a T containing in all 550–600 beds There is also an outpatients wing, attached to the main building, and separate buildings for mortuary, laundry (designed to serve a number of local hospitals), main kitchen, and garages, boiler house, and workshops The staff is housed in a nurses' home for 193 nurses, matron's bungalow, doctors' hostel, and engineers' house.

Within the main building, visitors move separately from hospital traffic until they reach their respective wards They use the three bed lifts arranged with doors at opposite sides so that access to the "hospital" corridor is separate from access to the visitors' waiting-spaces

The four main theatres and a plaster room are on the seventh floor of the treatment wing, and a small emergency theatre and X-ray room are placed near the ambulance entrance In the ward wing a typical unit consists of one 6-bed, five 4-bed, and five 1-bed wards

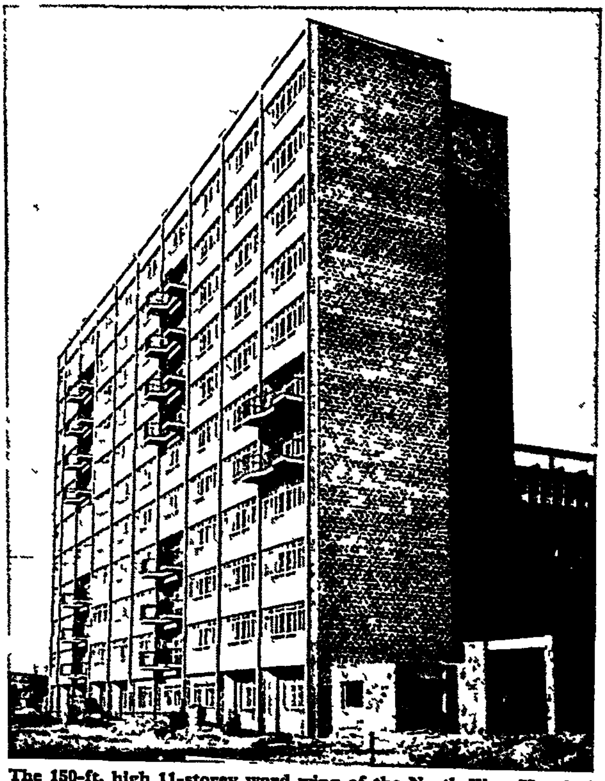
The external facings on the main building are largely precast concrete units, using exposed aggregates from local sources, and brickwork described as "buff-orange" The entrance to the hospital is presided over by a striking bronze figure (by F E McWilliam) of Princess Macha, who is reputed to have founded the first hospital in Ireland

The hospital replaces three small hospitals in Londonderry, one of which, the Londonderry City and County Hospital, is to be adapted for use as a special unit for sick old people

Architects F R S Yorke, E Rosenberg, C S Mardall, associate architect, J R B S -Penoyre, architects in charge, W G Lucas, A R Parry In association with H W Scatchard, architect to the Northern Ireland Hospitals Authority

Gransha

This £2 million mental hospital in the villa style is being built near Londonderry and the shores of Lough Foyle on a site acquired by the previous governing body of the hospital sixty years ago but hitherto little developed. The first building contract, now completed, provided villas for 90 patients, an admission unit for 60 patients, and a convalescent unit for 28 patients The present contract will supply three more villas (180 patients), an administration block, and patients' recreation halls Further contracts are expected to expand the hospital to 750 beds Accommodation is supplemented by the site's original buildings (185 beds), which are to be modernised. The first plan was to have 30–40 patients in each villa, but it was later decided to build each villa for 60 patients, arranging the accommodation so that a villa could be used if necessary as two self-contained units of 30 beds each



The 150-ft. high 11-storey ward wing of the North West Hospital, Altnagelvin, Londonderry, facing south-east to the Pass of Glenshane

Patients may be retained for several months in the central admission unit if the prospects of early return to the community are encouraging. Of the three villas for men at present in use, one is open and run by the patients themselves, another is open and supervised by a nurse, and the third is partly closed and supervised.

Architects J. M. Sheppard & Partners, London

Muckamore Abbey

Another £2 million has been devoted to this establishment for special-care (mentally defective) patients. Before 1948 there were no special colonies or institutions in Northern Ireland for persons requiring special care, and the only accommodation outside patients' homes was in mental hospitals. Muckamore Abbey is the first specially constructed colony in Northern Ireland. The Muckamore estate of 192 acres was acquired in 1949, and some female patients have since been accommodated in the existing house and in aluminium prefabricated buildings nearby. 154 more acres were acquired in 1951.

The patients are housed in villas each taking 40 or 50 patients. The male and female sites are divided by administration buildings, recreation hall, and school of nursing. There are separate workshops for male and female patients. The sick hospital of 70 beds will have 40 beds for general patients, 20 for tuberculous patients, and 10 isolation beds. A school for 350 children is to be built.

The prefabricated buildings are now being used for children, and when permanent quarters are ready for them the aluminium buildings will be used for old patients and young infirm patients in need of special care.

The aim is to provide a sheltered community, with very little restraint, where the handicapped can feel at home and useful, and to prepare them, if possible, for a return to the outside world.

Architects J M Sheppard & Partners, London, Ostick & Williams, Belfast

Geriatrics and Surgery

Wakehurst House,* the first unit of its kind designed and built in the United Kingdom for the rehabilitation of elderly invalids, is connected to the existing geriatric unit at Belfast City Hospital. The new building accommodates 40 men and 40 women in large open wards partitioned to give small units of 6 or 4 beds. A 16-bed wing on each of the two ward floors forms a self-contained long-stay unit, so that each ward sister has 40% of long-stay invalids, with the necessary staff to look after them and the other 24 patients undergoing rehabilitation. The 24-bed rehabilitation section includes a large exercise bay which gives more room for physical retraining than is found in the usual ward layout.

Nuffield House is an experimental theatre block which was opened in October, 1957, at Musgrave Park Hospital, Belfast. The plans were prepared as part of the Nuffield Provincial Hospitals Trust's Investigation into the Functions and Design of Hospitals. The completion of the building was the responsibility of the research body which succeeded the Investigation—the Division for Architectural Studies, which is part of the Nuffield Foundation. The unit contains 80 beds with operating-theatres, X-ray facilities, and a central sterile supply department. This department meets the whole demand for sterile goods used in treating patients in the hospital's 700 beds, and also supplies the operating-theatres with all sterile goods except surgical instruments. The equipping and running of the department have been closely studied and analysed, and modifications introduced from time to time.

This attractive building, which makes the adjoining temporary hospital huts of the late war look very temporary indeed, is really the first stage in a major scheme of reconstruction at Musgrave Park. The wartime buildings will go, and eventually the hospital will be almost entirely new.

This is only part of the building and reconstruction that has been completed or is in hand to improve the Health Service in Northern Ireland—from local-authority clinics to the £2,500,000 Ulster Hospital now building in Belfast. New acute hospitals will also be provided at Enniskillen, Coleraine, and Dungannon, and at the main teaching hospital centre (the Grosvenor Road site, Belfast) there will be a suite of new operating-theatres, a new eye, ear, nose, and throat hospital, an extension to the Royal Belfast Hospital for Sick Children, a new outpatient department, and a new dental hospital—at least £3 million of improvements.

THE AMERICAN VERSION OF THE WELFARE STATE

SINCE the great depression of the '30s precipitated the Social Security Act of 1935, welfare schemes in the United States have grown rapidly, but Mrs Dorothy Wilson's illuminating survey [1] shows that the American citizen is not offered the same help and support as in this country. In a Federation of equal States, where private enterprise and dislike of Government enterprise are strong, it is not surprising that the schemes should be complex and uneven. Much more is done than might be supposed from some American comments on the British system, but there are some sizable gaps.

Pensions

Under the Social Security Act of 1935 and its amendments of 1939, 1956, and 1958, Federal schemes provide old-age, survivors', and disability pensions which cover 90% of the gainfully occupied population (self-employed doctors being one of the principal groups excluded). The old-age pension scheme is completely self-financing employer and worker each pay a tax of $2^1/_2$% on the worker's earnings. Pensions are related to earnings, and range from about a third of earnings at the maximum level to about half at the lower end of the scale. Survivors' and disability pensions are also related to earnings.

Disability and Unemployment Allowances

A totally disabled worker becomes entitled to a pension at 50. Under that age he may be eligible for “compensation payments” or sickness benefit for a limited period, after which he will have to seek public assistance. Compensation for industrial injury covers less than four-fifths of the working population. Employers must supply medical aid to the injured, but in some States the amount of medical attention and the length of time for which it is given are limited.

The duration and size of unemployment benefits also vary from State to State.

Public Assistance

Public assistance is administered by each State and is much more selective than in Britain. Towards benefits for special categories—such as the aged, the blind, and the totally disabled—the State receives a Federal grant, but outside these categories assistance is the responsibility of the State Government. For the medical care of people on public assistance the Federal Government matches payments made by States and local authorities. Because of the absence of any national health-insurance scheme and the rising cost of medical care, more and more people are turning to public assistance when they are ill, and in 1957 about a tenth of the total expenditure on public assistance consisted of payments for medical care.

Since there are neither Federal funds nor supervision for general assistance, the standard varies greatly. In some places it is the same as for people in the special categories, in others it hardly exists. Thus, in a country with exceptionally high standards of living it is yet possible to be really destitute.

Sickness Benefits

There is no national system of sickness benefits, though rather more than half the workers are covered by schemes arranged on the initiative of employers, trade unions, and some State Governments The payments made are usually 50–60% of the wages, but for a limited period

---

* We hope to publish soon an article by Dr G F Adams, physician in charge of Wakehurst House, about the design and purpose of a hospital geriatric unit.

[1] America and the Welfare State *Planning*, 1960, 26 no 439 (Published by P E P, 16, Queen Anne's Gate, London, S W 1, at 5s)

Health Service

The Federal and State Governments provide medical care for certain groups of people and for certain diseases, either by payments to private hospitals and doctors or in public hospitals In 1958 some 30 million people (about a fifth of the population) received medical care in these ways About 23 million of them were Veterans or their dependants This specially favoured group have their own hospitals In 1958 almost a quarter of the total expenditure on medical care came from public funds

The ordinary citizen receives no Government help in time of illness Medical costs are high, and nearly three-quarters of the population cover themselves by some form of private hospital insurance But this leaves nearly 50 million people with none In 1958 the sums paid out under health-insurance policies covered only about a quarter of the nation's sickness bill.

COMPARATIVE COSTS

The United States social-security services absorb 8% of the nation's personal income, ours 11% We spend large sums on family allowances, have more retired pensioners, and draw more of our expenditure on health from public money (90%, compared with 25% in the U S A.)

In both countries retirement pensions were the heaviest item in the social-insurance budget. In the United Kingdom they claimed two-thirds of the social-insurance account, in the U S.A. a half In the U S.A. a single group, the Veterans, received 16% of all social expenditure, compared with 5% spent on war pensions in the British budget. Admittedly our war pensioners received further concealed help through other services, such as the N.H S

The U S.A. spent $22,000 million on health and medical care in 1957–58, but only about a quarter of this sum came from public money 20% came from private health-insurance schemes, and over half direct from the citizen's pocket, representing about 3% of his personal income In our country in the same year £660 million was spent on the N.H S The direct cost to the citizen was his weekly contribution of 2*s* 4½*d* and £27 million for N.H S charges for prescriptions, dentistry, glasses, and so on. In this country people are still paying considerable sums on private medical care—probably about a tenth of the total health bill.

SOME CONCLUSIONS

From her survey Mrs Wilson concludes that in both countries the lower-income groups probably owe more of their improved living standards to full employment and higher output than to the Welfare State. The British State offers more comprehensive cover and as a result has spread its benefits more thinly Many people are being helped who could afford to help themselves, while others are not getting all the help they need. As a result of this policy, capital expenditure in the health service has been severely restricted and there has been little left over for research

Our benefit schemes fall into the same pattern Nobody is left absolutely destitute, as can happen in the United States But our flat-rate benefit of 50*s* a week is inadequate for post-war needs, and in 1958 one in five of all households receiving retirement or unemployment benefits had to seek National Assistance

On the whole Mrs Wilson finds that the U S.A benefits do more than the British benefits to replace the income of those they help, but they are not comprehensive either for those they help or for the circumstances in which they give help She regards this as a serious flaw in the American version of the Welfare State.

In England Now

A Running Commentary by Peripatetic Correspondents

AT my alma mater, the subject of rugby was carefully avoided Only once did I venture as far as a first-round match, happily drawn against the only other side in London with an equal lack of talent. The winner was to meet the victor of Guy's *v* Mary's, and it soon became painfully obvious that this was an honour both sides were anxious to forego However, it must be conceded that the match was a masterly exhibition of how not to score any points, and even after two replays the score stood at a resolute draw of 0—0 Unfortunately, at the third replay, in one of the abundant free kicks which characterised this series, someone on our side (possibly distracted by the vociferous exertions of a small band of female students) inadvertently kicked the ball over the bar Thereafter, the score stood firmly at 3—0 The subsequent encounter with Guy's, when the score was somewhat unnecessarily 98—0, realised our worst fears

However a new allegiance has changed my attitude, and last Wednesday I not only watched my hospital play in the Cup Final but saw it bring off a resounding victory The preliminaries to the match were elaborate A band paced the pitch in splendid style and the loud cheer greeting the request for non-players to leave the field was no reflection on their performance, which was at once manly and stirring, though at no time could any tune be actually discerned. The far end of the field was dominated by a heavily armoured green-grocer's cart which successfully repulsed the most determined assaults with a hail of decomposing merchandise

Since the victors had many moments of fine play and superiority, loud expressions of parochial pride came without difficulty, punctuated as they were by violent explosions from a heavy cannon mounted at the far end of the field on a vehicle which had clearly seen better days From the vehemence of your correspondent's endorsements of such cries as "Kill the b——s!", few would have guessed that they sprang from loyalty by adoption.

* * *

Some time ago[1] I described in affecting terms—at least they affected me—how the path through Blossom Wood had become overgrown because Ted had got a motor-bike and no longer walked along it to his work. Now it is back again—even more so—and again the cause is the internal combustion engine

Reablement was phased, as we say when we haven't got enough money to rebuild a hospital all at once Stage I was heralded by what sounded like a machine-gun battle in the wood, and the following Sunday the lane was blocked by scores of cars and motor-cycles whose occupants had come to watch—and incidentally break down my hedge—a motor-cycle "scramble" with 150 entrants from all over the country The riders went down a wet ditch, along a stream, through a swamp, and then up an almost vertical muddy slope which, though allowed to do almost anything except carry their bikes on their shoulders, not one of them succeeded in climbing Quite incidentally they drove along the old path through the wood and opened it up again.

Stage II started with the arrival of a pile of logs with curious orange centres, where the path enters Blossom Wood from the lane. Reconnaissance showed them to be alder logs from the banks of the stream in the field beyond They had been hauled on a tractor through the wood, and the path was now a broad, and unusable, mud-track. My spies tell me the logs are awaiting transport to a manufacturer of toys down Chichester way Alder wood has not many uses now that clogs are no longer fashionable in the North, and why should a toy-maker want it? The answer—no splinters

* * *

It must be nice to have one's name attached to a disease which one has discovered, and in the past those who like to collect rare conditions and to publish accounts of a case or three had grounds for hoping that such an honour would come their way Now Asher has shown us that this will not happen unless we are possessed of an extraordinary moniker Having an utterly unmemorable name I have given up the struggle Instead of inventing diseases to go with my name I have turned to inventing names to go with the diseases This is a good thing because in our area the professor is very keen on classification and has provided us with a modification of the *Nomenclature of Diseases* which covers every eventuality, he hopes However we are always adding to it When I sent in "Queer-shaped nut" for a child whose head was not exactly plagiocephalic but nevertheless out of the true, I was rebuked for levity I am now deadly serious, and here is the result.

---

[1] *Lancet*, 1958, ii, 521

I often see children who are fit and well but who are considered by their parents to be diseased because they have been comparing them with other children in the family for so-called lateness in talking, thinness, fatness, and so on. Well now *dys*—difficulty, *confero*—by comparison, *sibl*—with a sibling, *osis*—osis *Dysconferosiblosis*, easy There is an even more serious disorder in which it is the neighbours' children who are used as the yardstick. This is covered by the designation *Dysconferojoneses* I thought that perhaps that was the end, but only yesterday I came across a worse case The child, a late talker, was being compared with not only his elder sister, who started to talk early and has never stopped, but also with his younger brother, who is grosser, and with the neighbours' brat who can sing and play the piano, and is obviously headed for the top ten There is only one thing for it I am afraid *Dysconferojonescumsiblosis* In Polish, and more neatly, *Dyskjksosis*

Apart from this I often see children whose psychological troubles seem to stem from the fact that one or both parents are foreigners The child has to come to terms with two languages at the same time, and while the more brilliant ones can do it easily the duller ones become confused and may show various behaviour disorders No *osis* here, let's just call it the Tower of Babel syndrome

* * *

If formal dining out is the socially accepted method of suicide for elderly gentlemen, then the cocktail party must be a close second Talking blah in an upright position for ninety minutes does nothing for the spine, and only 'Breathalyzer' tests for all motorists after 7 P M will save us The dinners seem to consist of stuffing food into stomachs already suffering from too much for too long What a good thing it would be if we swopped with a teen-age rock-an'-roll outfit They could have the seven courses and we could have the milk and sandwiches A creaky session of R and R for afters might not be elegant but it would be good for the figure

* * *

From the point of view of the reporter sent by the local weekly newspaper it was a more than usually dull meeting of the executive council Not a single doctor anonymously reprimanded, only one dentist fined a trifling matter of £4 Nothing meaty at all The whole afternoon was spent on the need—long established but still unfulfilled—for a pædiatrician in the area A full account of what had been said by the H M C to the R H B, and of the comments of the L M C on the R H B's reply—a bewildering collection of letters and initials, all about a pædiatrician, as yet non-existent Back to his office went the reporter to write his account of the meeting What would attract the reader's eye to such a dreary subject? What simple phrase would carry the required punch? At last he found it Printed in splendidly arresting heavy type his headline ran CARE OF COUNTY FEET—CONSULTANT SERVICE ASKED FOR.

* * *

INFORMATION PLEASE

To be, or not to be, that is the question—
And since 'tis equiprobable, the choice
Requires but one small Bit of Information
Whether to live—eat, drink, and sleep
(Though in that sleep what dreams may come)
Or die, and dying write another name
Among the actuarial statistics Ay,
The little more and yet how much it is,
It needs one Bit—the Bit I do not have

Letters to the Editor

THEATRE STAFF

SIR,—The patient's limbs slipping off the table because the staff do not know how to fix them in position, the diathermy that does not work because it has not been plugged in to the wall, the abdomen reopened at the end of a long operation because someone has taken a swab outside in a bucket—how well we know and how sick we are of this sorry tale of incident and accident that punctuate the progress of our operating-lists I have had a junior nurse fill up the cystoscopy cistern with boiling water from the steriliser I have asked a nurse to shut the door only to discover that she did not know enough English to understand what I meant I am regularly stopping to show nurses how to tie on a gown, and giving them the warnings without which a casual spectator would not be allowed into the operating-theatre Surely this is not necessary "Oh, but our nurses must get their training The General Nursing Council " But trained for what? Not one of these girls will ever put her nose inside a theatre again once she leaves her training-school Why train them for a task they will never be called on to undertake?

By all means let the Dean of the Institute of Basic Medical Sciences (March 12, p 604) do something about it if he can, but I doubt whether he will succeed the opposition is too well entrenched And why does he start by appealing to the Ministry? This is a matter for internal decisions in the first place, but I suppose that means raising it in committee, which is the surest method of shelving the whole business for another decade or so

London, W 1 STEPHEN POWER

ANTI-SMOKING CAMPAIGN

SIR,—Whilst agreeing with the authors of the paper (Feb 6) on the Efficacy of an Anti-Smoking Campaign that the status of health education is not high enough, I feel that the lack of success achieved as a result of their considerable efforts in their campaign may be due to the very reasons mentioned in their preamble It is unfortunate that before embarking upon such a vast and costly enterprise, so little attention was paid to the scientific evidence already accumulated on the conduct of health-education programmes and the use of audiovisual media in this field

The main object of health-education activities is the alteration of individual and community attitudes leading to changes in patterns of behaviour conducive to positive health It is now well known from studies, both at home and abroad, that this end is best achieved when the educationalist uses a personal and socratic approach rather than impersonal and didactic methods and media The latter are useful for stage-setting and the creation of interest in specific topics, particularly in the field of environmental health They do little to create the feeling of *total personal involvement* in matters of individual health and wellbeing This is especially true when the recipient of the didactic approach has been the subject of considerable propaganda bombardment over a long period of time from the opposing viewpoints Under these circumstances attitude and habit changes are rarely brought about by the academic and intellectual revelations associated with didactic methods (witness the still large number of the profession who continue to smoke) Personal conviction develops as a result of ingestion and incubation of facts followed by social rumination, particularly when this takes place under specially created and controlled circumstances Opportunities for these social exchanges should be provided in the course of any campaign by using such methods as the group and arena discussion, individual and group interviews, and open forums These are known to be extremely effective in creating within the individual the sense of personal involvement leading to the alteration of attitude and behaviour patterns Such organisations as the Central Council for Health Education have accumulated considerable evidence in favour of the use of these methods In the campaign described considerable use was made of mass publicity media and didactic methods No mention was made of the use of these personal and socratic techniques, nor does it appear that consideration has been given to the possibility of a follow-up campaign, in which they would be used.

A social health problem of this magnitude demands continuous personal rather than financial effort and one in which all who have a responsibility in the wellbeing and care of the community as part of their day-to-day duties should be involved. In addition to the doctors, there are health visitors, district nurses, public-health inspectors, &c., who have a considerable part to play and can make a very definite contribution, at their own level of professional activity It was indeed unfortunate that no programme of in-service training for these groups appeared as part of the campaign planning

The negative findings of this project are of great value because they demonstrate the ineffectiveness of this type of impersonal campaign They also show that the media used were unsuitable, thus underlining the need for proper pretesting and evaluation It would be of interest to know whether low-intensity work, using the personal methods described, is contemplated and whether in the long run this will have a greater and more lasting effect on the recipients of the original campaign

Sheffield F St D Rowntree

PLACENTA PRÆVIA

SIR,—It is indeed difficult to follow Professor Macafee's argument (Feb 27) against radiological investigation in cases of placenta prævia, and since he has mentioned my name I take issue with him

He begins by stating that "it is in cases of antepartum hæmorrhage at 30–37 weeks that X-ray diagnosis may be of assistance" Why then is he personally "relieved to find that even some of its earlier advocates have now discarded this type of examination?"

Again, immediately after this admission he states that "at this stage accurate clinical diagnosis can be difficult " Yet he does not suggest that, because clinical diagnosis can be difficult, clinical examination should be given up Quoting me, he says that because I deny that a single lateral view is adequate for the radiological diagnosis of the placental site (and emphasise the point by stating that, "even with four films, carefully planned, really adequate opinion is, not infrequently, very difficult to offer, even in expert hands") and because I lay stress on the *difficulty* of precise diagnosis, I have completely condemned this method of examination. If this use of a quotation out of context can be termed "argument", I still do not accept it.

Professor Macafee says that placentography has not been done for some years in his hospital. Such a statement hardly qualifies him to argue with those who still use the method daily May I remind him that no radiologist sends himself cases it is his colleagues who continue to refer cases to him because they believe that he can show the placental site accurately Professor Macafee may be interested to know that since 1954 a single obstetrical unit, situated some 4 miles from Saint Mary's Hospitals, has referred an average of 56 cases per annum (inpatients as well as outpatients) for demonstration of the placental site Already the indications are that this average will be exceeded in 1960 Apart from this, placental-site requests at Saint Mary's Hospitals amounted to 265 in 1959 These figures do not suggest that the method has fallen, or is falling, into disrepute.

Professor Macafee is very far from the truth if he thinks that those obstetricians who have an intimate up-to-date knowledge of expert radiological diagnosis "completely condemn" the method He should come and see for himself exactly how the method can be used to his advantage, and thereafter attempt to convince my obstetrical colleagues of the error of their ways in referring cases for radiological demonstration of the placental site

Department of Radiology,
Saint Mary's Hospital,
Manchester, 13 J Blair Hartley

ORAL CONTRACEPTIVES

SIR,—It should be clearly stated that the orally active progestational steroids have been in continuous use as a contraceptive in Puerto Rico for only four years Whilst Dr Mears (Feb 27) is correct in stating that so far no harmful effects have been reported, it should be remembered that their use as an oral contraceptive will involve interrupted administration over a woman's entire reproductive life Many more years of experience will have to be acquired before it can be safely stated that they are free from serious harmful effects, such as carcinogenic changes Even after many years of experience with œstrogenic steroids, there is doubt about this point in the minds of several authorities

It should also be pointed out that these substances can at present be obtained free of prescription (though a recent recommendation of the Poisons Board [1] seeks to limit them to issue on medical prescription) Whilst the limited clinical trials in their use as an oral contraceptive planned in this country will no doubt be conducted under the strictest medical supervision, the dosage and method of administration are being freely discussed in the Press, and there is nothing to stop a woman from trying out their use for herself, without medical supervision.

This group of compounds is certainly not free from side-effects which can include breakthrough bleeding, nausea, headache and dizziness, breast soreness and skin rash, and masculinising effects with some of the compounds available. Marked change of libido is common and I have found them of considerable value in this respect for the treatment of nymphomania

It is clear that the experimental use of these compounds as an oral contraceptive is only justifiable under strictest medical supervision, and action should be taken to have these compounds included under category III of the Poison Schedule along with œstrogenic steroids, to insure that these cannot be used indiscriminately

London, W 1 G Barry Carruthers

SIR,—Although long threatened I hope some others groaned to learn from the daily Press that an oral contraceptive had reached clinical trial in Birmingham. Dr Mears added to the gloom until she hopefully said that these drugs are not really suitable for prescribing at present, only to relapse in her last paragraph by admitting "we" are looking for something simpler and less expensive, for use in large-scale population control in undeveloped countries It is ironic that we in the West are only contemplating this measure at all because we are ourselves a sprawling population and, I suppose, undeveloped as well, but that is not my real point

This method of birth control contains two offences against humanity which other methods do not have. The first offence is suppression of normal physiological function. I see no difference in this approach from the requests of those earnest young men who occasionally arrive in the consulting-room and ask if their vasa can be tied. We are surely agreed what we do with them say no, politely, and if that fails to sink, ask them what kind of animals they think we operate on.

---

[1] See *Lancet*, Feb 20, 1960, p 446

The method secondly offends by not being an open and unconcealed contract between the parties It is possible that either the man or woman could see that the pill is taken or given surreptitiously without consent or knowledge of the other, or worse, it could be given by an outside agent either for public or private purposes

These are basal offences which it is difficult to reconcile with any code of morals hitherto held in this end of Europe The other complications, such as genital or mammary cancer, risk of mutation, &c, would presumably be found out later, but it seems to me that a profession which is prepared to handle this drug in this country is betraying a sacred heritage The opportunity is still open—refuse now to handle it, before it is too late

Manchester OLIVER JELLY

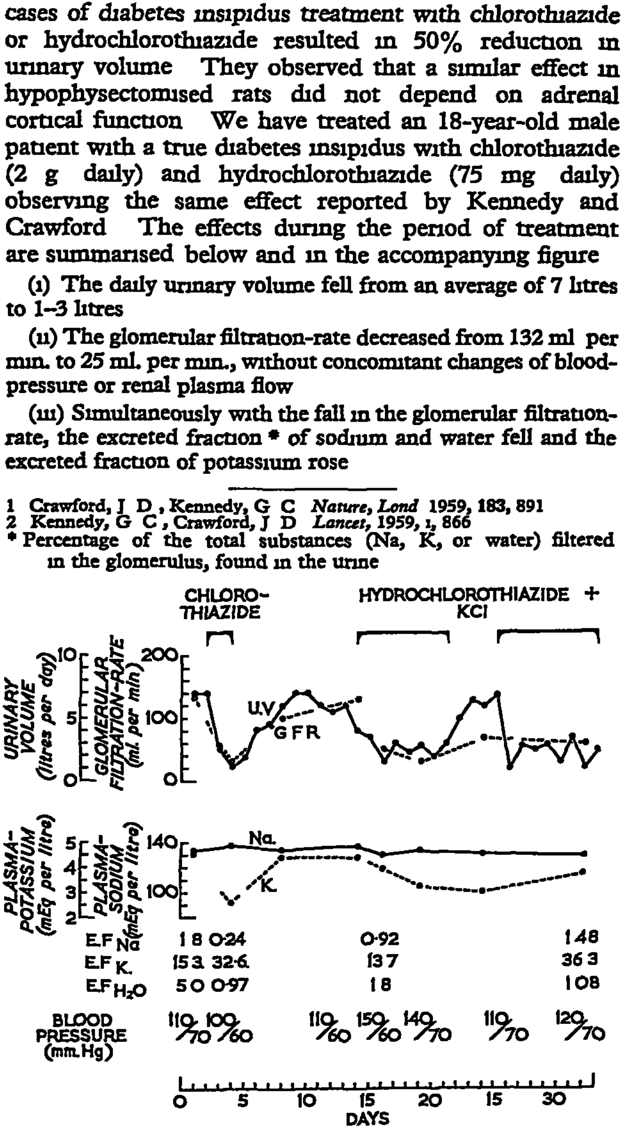
HYDROCHLOROTHIAZIDE AND DIABETES INSIPIDUS

SIR,—Kennedy and Crawford [1] [2] reported that in two cases of diabetes insipidus treatment with chlorothiazide or hydrochlorothiazide resulted in 50% reduction in urinary volume They observed that a similar effect in hypophysectomised rats did not depend on adrenal cortical function We have treated an 18-year-old male patient with a true diabetes insipidus with chlorothiazide (2 g daily) and hydrochlorothiazide (75 mg daily) observing the same effect reported by Kennedy and Crawford The effects during the period of treatment are summarised below and in the accompanying figure

(i) The daily urinary volume fell from an average of 7 litres to 1–3 litres

(ii) The glomerular filtration-rate decreased from 132 ml per min. to 25 ml. per min., without concomitant changes of blood-pressure or renal plasma flow

(iii) Simultaneously with the fall in the glomerular filtration-rate, the excreted fraction * of sodium and water fell and the excreted fraction of potassium rose



Changes in urinary volume, glomerular filtration-rate, plasma-sodium and plasma-potassium, sodium, potassium, and water excreted fractions, and blood-pressure of a patient with true diabetes insipidus, treated with chlorothiazide (2 g daily), hydrochlorothiazide (75 mg daily), and potassium chloride (2 g daily)

(iv) Plasma-sodium concentration remained unchanged, while plasma-potassium decreased sharply, inducing a secondary hypokalæmic alkalosis

(v) The decrease in glomerular filtration-rate induced by hydrochlorothiazide was only partially restored after the subcutaneous administration of 30 units of aqueous pitressin which induced a large increase in the excreted fraction of sodium and did not change the excreted fractions of water and potassium

These effects on renal function were maintained throughout the treatment period—i e, no escape phenomena were observed The total recovery of diuresis followed 2 days after the drug was stopped, and the effect on glomerular filtration-rate persisted for 4 to 6 days

These results support the view that the paradoxical effect of this diuretic drug in diabetes insipidus is due to a decrease in glomerular filtration-rate to much below normal

A PLEA FOR MORE NECROPSIES

SIR,—As an answer to the difficult problems of diagnosis is usually found in a postmortem examination, it may be of interest to record the results of 223 necropsies on patients from the geriatric wards of Tooting Bec Hospital The diagnosis during life was corroborated after death in 212 cases, so that 11 remained in which either a wrong diagnosis had been made or important conditions were revealed that had escaped observation during the patient's life

(1) Aged 74 Sudden death from coronary thrombosis verified at necropsy A carcinoma of the sigmoid colon was unexpectedly found

(2) Aged 55 Here again coronary thrombosis was given as cause of death The patient had craniovascular syphilis with pareses and seizures Necropsy revealed a gastric carcinoma

(3) Aged 75 Ten days after admission with no history of pulmonary disease, the patient died, apparently of bronchopneumonia At necropsy consolidated and caseating tuberculous lesions of the lungs came to light

(4) Aged 62 Lobar pneumonia (cause of death) was combined with cirrhosis of the liver, which had not been detected during life

(5) Aged 76 A diabetic had an apoplectic seizure six weeks before he died, death being attributed to cerebral thrombosis Necropsy showed an undiagnosed primary carcinoma of the liver without secondary growths

(6) Aged 70 Cerebral hæmorrhage was associated with a hæmangiomatous angioplastic meningioma occupying a third of the rostral part of the right temporal lobe

(7) Aged 91 Senility was given as the sole cause of death Necropsy disclosed carcinoma of the prostate with masses of metastases in the liver and one in the cortex of the left kidney The right kidney showed hydronephosis

(8) Aged 85 In this case of chronic lymphatic leukæmia a previously undiagnosed carcinoma of the stomach was found

(9) Aged 93 This patient in whom only chronic bronchitis had been diagnosed in life was found at necropsy to have an oat-cell bronchial carcinoma spreading through the lung tissue, and a metastasis in one adrenal gland

(10) Aged 74 A senile dement was admitted with the diagnosis of carcinoma of the bladder with cerebral metastases Postmortem examination revealed a benign papilloma of the bladder and a moderately enlarged non-malignant prostate with localised abscess formation The brain presented no abnormality except senile vascular changes

(11) Aged 75 In this patient, who died of bronchopneumonia and cardiovascular degeneration, a diaphragmatic gastric hernia was unexpectedly discovered at necropsy

The number of diagnostic failures (roughly 5% out of 223) discovered post mortem is comparatively small, but these errors and omissions would undoubtedly be revealed in increasing numbers in the many cases where the cause of death has not been verified by necropsy

In no less than 6 of these cases some unsuspected form of cancer was discovered at necropsy. Otherwise, the cause of death would probably have been given as cardiovascular degeneration. Statistics for the causes of death in general and for malignant disease in particular thus cannot claim any degree of accuracy, and yet statistics are held to be an important basis for research and preventive medicine.

It seems that more use should be made of postmortem examinations. It may be necessary to overcome the traditional objection of the public to necropsy, but if the assurance is given that the human form is treated with respect and reverence, and if it is explained that there is great benefit for the living to be gained from examination of the dead, it should be possible to overcome prejudice.

Geriatric Department,
Tooting Bec Hospital,
London, S.W.17.

NOEL ALDER

TREATMENT OF ORGANOPHOSPHORUS POISONING

SIR,—Among the supportive measures mentioned by Edson[1] are postural drainage and oxygen for the relief of pulmonary œdema and respiratory distress. In the most severe and acute poisoning, with predominant asphyxia, only tracheal intubation, active ventilation, and bronchial aspiration can preserve life until atropine and other medical measures become effective.

We have treated in this way 5 persons poisoned by parathion.

They arrived at hospital on the point of death and 3 of them were saved. Muscular relaxation and a comatose state make it easy to intubate without curare, and the tube is well tolerated even when consciousness and spontaneous breathing return. In 1 case a tube was kept in successfully for twelve hours.

We believe that many deaths might be avoided by these simple measures, which gain in efficacy if applied immediately the patient enters hospital.

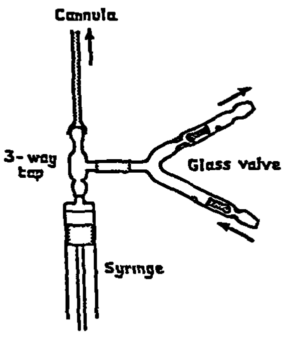
Ospedale Civile di Oristano,
Cagliari, Italy.

GIULIANO TESTA.

A VALVE FOR EXCHANGE TRANSFUSIONS

SIR,—For the past $2^1/_2$ years at this hospital we have been using a 2-way automatic glass valve in performing exchange transfusions on babies, together with one 3-way metal tap (see figure). We have found it extremely satisfactory.

Its only defect is a slight increase in the dead space, but this has no practical effect on the exchange. It is, of course, only a gadget, but it is labour-saving and allows the operator to have the tap less on his mind.



The valve was first designed by Dr Henry W. Kaessler, of New York, and was made and distributed by the Ringler-Rados Surgical Corp., 3958, Broadway, New York, 32, who have kindly allowed this valve to be made and marketed in this country. The valve is now obtainable from the Laboratory Glass-blowers Co., Valley Works, Lane End Road, Sands, High Wycombe, Bucks, at a cost of 21s. It is not identical with the American model, but it has proved satisfactory, and I think is well worth the attention of all those who have to do exchange transfusions.

When using the valve the bottle containing the blood must be at a lower level than the valve itself or siphoning back will occur.

It should be noted that syphoning from the catheter into the waste tube may occur if the syringe is removed from the tap. The waste tube must always be clamped before removing the syringe.

Queen Charlotte's
Maternity Hospital,
London, W.12.

A. P. NORMAN

ACUTE HÆMOLYTIC ANÆMIA AND PHENACETIN

SIR,—In connection with Dr Houston and Dr Barlow's report[1] I should like to record a similar experience.

The patient was a charwoman, aged 28, with no family history of nervous or mental diseases, whose childhood, home, and marriage had been unhappy. At the age of 17 she had shown X-ray evidence of peptic ulcer. After an acute psychic trauma concerned with a new love-affair, she consumed 60 'Diallyphen' tablets containing 30 g. phenacetin (plus 1·8 g. allobarbitone).

Admitted to hospital about 12 hours later, on Aug. 12, 1959, she was deeply unconscious and cyanosed, with deep frequent respiration. Her pupils were medium-sized, reacting to light. Reflexes normal. Blood-pressure 100/80 mm. Hg, pulse-rate 108. Shortly after admission, she was given methylene-blue, after the blood had been found to contain 51% methæmoglobin. She gradually rallied, and on the 5th day she was completely orientated. Since, however, the hæmoglobin level was rapidly decreasing, the erythrocyte sedimentation-rate rising, and jaundice increasing, with dark urine and normally coloured stools, the hæmolytic anæmia was treated with prednisone and she made a rapid recovery. Steroid therapy was withdrawn after 17 days, and she was discharged in good health. Hæmoglobin level and reticulocyte count two weeks after discharge were normal.

Hillerød, Denmark.

KLAUS VOLLMOND

"LIES, DAMNED LIES, AND STATISTICS"

SIR,—Disraeli's triad is a witty expression of the commonly held opinion that "you can prove anything by statistics". Be that as it may, statistics very largely govern medical and other forms of scientific research, in spite of doubts which may arise in the minds of the "good doctor" and the experienced clinician, who sometimes have the intuition that many factors of importance transcend the realm of ponderables.

Many doctors have expressed doubts about the general applicability of statistical conclusions, and, still speaking from a medical rather than a lay point of view, I should like to contribute to the case that "you can prove anything by statistics". The reasons for holding such a view are broadly as follows.

The validity of statistics never transcends the limits set by the criteria initially chosen to define a given study. These criteria naturally determine the data obtained, and these data alone constitute the raw material from which the statistical generalisations (or "probabilities") finally emerge. The most important point here, albeit a simple one, is that the criteria chosen directly govern the end-results, which, so to speak, are a "function" of the former. (That is to say, the results can never be "greater" than the original criteria from which they derive.) A modification of the criteria clearly means an alteration in the results.

The main danger here is not simply that a deliberately weighted choice of criteria (calculated to satisfy some interest) is sufficient to secure results agreeable to that interest. (This is possible, and it can be difficult to detect.) Much more alarming, and more common, is what can occur even when the choice of criteria (in, for example, a clinical trial) springs from a would-be "objective" intention. (Nearly always such an intention is painfully naïve in operation.) In spite of would-be objectivity, the way here is inevitably wide open for major self-deception. The reason for this is as follows. The biological situation, by its very nature, is always indefinitely complex. For this reason it is necessary to select a set of ponderables which is restricted to manageable proportions, and it is in the nature of things that this selection, however just the intention, cannot fail to be arbitrary Explicit definition of the set of criteria selected for study is usually held to be a sufficient safeguard against subsequent misinterpretation. In many minds, however, statistical conclusions deriving from a limited set of "arbitrarily" defined criteria are allowed to spill over on to a much wider field of reference Experience shows that it is all too easy to forget the limitations inherent in statistics by definition.

---

[1] *Lancet*, 1959, i, 1204.

[1] *Lancet*, 1959, ii, 1062.

A point of more fundamental importance is that data collected for statistical analysis are as "quantitative" as can be, for the reason that "qualitative" overtones are not susceptible of measurement, and, as every quality is unique in itself, cannot be added to one another to form a series of "similars" (like numerical units), about which alone "mathematical" statements can validly be made This exclusion of real, albeit immeasurable, factors is the reason why statistical results always exhibit a marked artificial character, which, if underestimated or unsuspected, can lead to conclusions which are both misleading and unrealistic

I submit that woolly thinking on the question of statistics has become widespread and habitual, and that this state of affairs has had enormous repercussions on our life and knowledge in general Scrupulously realistic scrutiny of statistical results and implacably clear thinking about the nature of statistics itself are urgent intellectual necessities *

Manchester W S STODDART

PERTHES' DISEASE

SIR,—Our experience is quite contrary to Professor Trueta's statement (Feb 13) that true Perthes' disease is exceptional in the Negro race We say "true" Perthes' disease to draw a clear distinction between classical juvenile osteochondritis and the faintly similar changes found in the femoral heads of patients who have sickling disease, they are separate entities, and both certainly occur in the African

University College Hospital, Ibadan W P COCKSHOTT
Mpilo Hospital, Bulawayo P E S PALMER

LIPÆMIA AND FIBRINOLYTIC POTENTIALITY

SIR,—Dr Hougie and Dr Ayers (Jan 23) state that we found that "the fibrinolytic activity of blood tends to be lower in people with a high serum cholesterol than in those with a lower level" Now, at the time we wrote the article [1] we had not done that experiment, but we have since, and are interested to note that Hougie and Ayers find as we have done that the cholesterol level has no effect on the level of fasting fibrinolytic activity

In the work referred to by Hougie and Ayers, we artificially altered the cholesterol content of normal plasma with various solvents and found a relationship between the residual cholesterol and the fibrinolytic activity of the treated plasma

It is of great interest and importance to note how small changes in technique alter the results of most of the current methods for estimating fibrinolytic activity We left our clots in their own serum, and in the majority of cases there was still clot present after 24 hours' incubation at 37°C Hougie and Ayers remove their clots from the serum, wash them in buffer, and leave them in buffer, and find considerable degrees of lysis, even up to 100%, in as short a time as 1 hour This suggests that the serum and what it contains may be rather important when one wishes to study factors inhibitory to fibrinolysis when measured by a plasma-dilution technique

Our most recent work (to be published) suggests that proactivator is activator bound by an inhibitor, a cholesterol and triglyceride-containing protein —Proactivator, we find, has slight affinity for fibrin, but activator has marked affinity On the lysis of the clot, activator is released again Thus, I envisage that in Hougie and Ayers' method the activator is available over and over again for activation of plasminogen, also adsorbed on the fibrin, resulting in rapid lysis The activator inhibitor is present in the serum and has been removed in their method, but not in ours, and this may account for the differing results

AUTOGENOUS VACCINES AND THE COMMON COLD

SIR,—May we refer briefly to the comments of Dr Ritchie (Feb 27) and Dr Heald (March 5)?

A feature of Dr Ritchie's trials was that the vaccines were prepared from unselected bacteria isolated from patients' own saliva It seemed possible that his successful results were due to this rather than to his dosage schedule The work which was undertaken on R A F flying pupils was not intended to repeat the work of Dr Ritchie In our trial his method of vaccine production was copied but we realised that we could not expect healthy young men, who were in no way worried about colds, to volunteer for a long series of injections Nevertheless, as the catarrhal complications of the common cold seriously interfere with flying, it seemed worth investigating a modification of Dr Ritchie's scheme since his own results had suggested that the catarrhal stage could be reduced, even although the incidence of the primary infections were not This was the advantage we sought, provided it could be achieved with a reasonably small number of injections Although for practical purposes we were unsuccessful, we cannot agree with Dr Ritchie that, because we found his method impracticable, we should not have investigated an alternative procedure

ACROPARÆSTHESIÆ AND THE CARPAL-TUNNEL SYNDROME

SIR,—Your annotation of Feb 27 and the article by Dr Wilkinson on the carpal-tunnel syndrome in pregnancy call for some comment

The syndrome of acroparæsthesia, as defined by Kremer,[1] is a well-defined symptom-complex that has only one cause—namely, median-nerve compression in the carpal tunnel Lesions in the vicinity of the thoracic outlet or axillary inlet do not cause anything like this group of symptoms, and I think it is a pity that this mythical entity has been disinterred so soon after it has been buried Symptoms of cervical-root compression in cervical spondylosis are usually easily distinguished from acroparæsthesia, but the two conditions are very common and it is not strange that they occasionally coexist. However, Dr Wilkinson's finding of root signs in 7 out of 14 cases of acroparæsthesia in pregnancy is surely very unusual and is a much greater incidence than I personally have found.

Dr Wilkinson treated 3 cases with splinting of the wrist and in only 1 was there a good result, but I have treated many such cases with splinting, and in my view it is the treatment of choice for acroparæsthesia in pregnancy

SCREENING TEST FOR TYPHOID CARRIERS

SIR,—In a recent paper,[2] Schubert, Edwards, and Ramsey described the extraction of Vi antigen from *Citrobacter ballerupensis* (*Salmonella ballerup*) by hot saline According to these authors, sheep erythrocytes exposed to such an extract absorbed the Vi antigen and thus provided a reagent that was sufficiently sensitive and specific to be useful for a Vi hæmagglutination screening test for the detection of typhoid carriers In view of the apparent attractions offered by the procedure described—ease of preparation of the antigen and specificity of the test as reported in the paper—I think that it is worth while to give a resumé of my findings during a trial of this method

It was found at an early stage that a high proportion of the human sera tested contained agglutinins for sheep erythrocytes As it was impracticable to carry out a preliminary absorption of these agglutinins, human group-O Rh-negative erythrocytes were substituted for sheep cells In all other respects the hæmagglutination tests were carried out as described by Schubert et al It was confirmed that sera known to contain Vi antibody agglutinated the sensitised erythrocytes However, while Schubert et al did not report any false-positive hæmagglutination reactions in their control series, I found, with more than 300 sera from randomly selected "normal" persons, that 20% gave positive reactions with the sensitised red cells In contrast, only about 1% of these sera were regarded as positive in the routine agglutination test with a suspension of *Salmonella typhi* ViI Human erythrocytes sensitised with purified Vi antigen yielded results similar to those of the ViI suspension In the majority of instances, the antibody causing agglutination of Ballerup-sensitised erythrocytes in normal sera was not absorbed by ViI suspension or neutralised by pure Vi antigen Controls of the human erythrocytes which had not been exposed to Ballerup extracts were invariably negative

The conclusions may therefore be drawn that the antibody that agglutinated the Ballerup-sensitised red cells in the normal controls was not a Vi antibody, that the saline extract of *Citrobacter ballerupensis* contains antigens (perhaps O antigens) in addition to the Vi antigen, and that these additional antigens are adsorbed to erythrocytes, thus introducing a sensitivity which is not connected with the Vi antigen and its corresponding antibody

As about 20% of the sera of normal persons in this country appear to contain antibodies to these non-Vi antigens, the test is clearly unsatisfactory for use here

These findings will be reported in detail at a later date

METHYLTHIOURACIL IN THYROTOXICOSIS

SIR,—Professor Wayne's references (Feb 20) to methylthiouracil prompt me to record the long-term follow-up of 100 consecutive cases of thyrotoxicosis personally treated with this drug when it was in vogue between the years 1947 and 1954

Treatment was maintained for a year with regular out-patient observation for a further year and intermittently thereafter Thyroidectomy was suggested if signs of relapse occurred, and also to any patient who had a large goitre as soon as he or she became euthyroid There were 90 women and 10 men, the average age being 55 The results, surveyed this year, are as follows

Well after discontinuing treatment	43
Thyroidectomy for relapse or goitre	37
Continuing treatment, refusing operation	13
Lost from follow-up	4
Dead, while on treatment (carcinoma of breast, cerebral embolus, degenerative cardiac failure)	3

No case of agranulocytosis occurred Treatment only had to be stopped once, for drug rash and fever, but it was possible to resume again after an interval The fatal case of cerebral embolus arose during the change from fibrillation to sinus rhythm, quinidine had not been given Auricular flutter, which has been erroneously described as a toxic effect of anti-thyroid drugs, was noted twice in the transition from fibrillation to sinus rhythm It is, of course, not a toxic effect, but a consequence of the mechanism by which this change is achieved

The chance of relapse increases with the period of observation, but it is clear that an appreciable number of patients get a worthwhile remission on this drug Even if it is necessary to give a second course at some later crisis in their lives, they may prefer it to thyroidectomy

POTASSIUM PERCHLORATE IN THYROTOXICOSIS

SIR,—In their article of Feb 20 on the relative merits of various anti-thyroid drugs, Dr Crooks and Professor Wayne describe a case where agranulocytosis developed during the third week of treatment with potassium perchlorate in a dose of 1500 mg a day Later they say "If the use of potassium perchlorate increases we should not be surprised to learn that this serious condition may be associated with lower doses or that the bone-marrow may be affected in other ways"

In the following case both agranulocytosis and thrombocytopenia occurred after twelve days' treatment with 1000 mg a day in divided doses

The patient was a married woman, aged 56, suffering from classical Graves' disease The basal metabolic rate (sedated) was +56% before treatment. On Feb 7 treatment began with potassium perchlorate 1000 mg daily At this time her white-cell count was 5000 per c.mm She remained well until Feb 19, when she developed a high temperature, followed by a punctate erythema on the extensor surfaces of her limbs two days later The white-cell count on Feb 21 was 2000 per c mm (polymorphonuclears 1200) Treatment with potassium perchlorate was stopped on Feb 22 when the total polymorphonuclear-count was 980 per c mm and platelets 60,000 per c mm A marrow puncture on the same date showed some toxic changes in the granulocyte precursors, no evidence of any maturation arrest, but a prominent number of eosinophils The rash subsided on Feb 24 By Feb 29 the total polymorphonuclear-count had risen to 3250 per c mm and the platelets to 100,000 per c mm The platelet-count was 220,000 on March 4 and the polymorphonuclear-count was 4850 The temperature returned to normal on March 3

EARLY DIAGNOSIS OF PREGNANCY

SIR,—A few months ago, I read with great interest your correspondents' letters on tests for the early diagnosis of pregnancy Dr Forster[1] and Dr Kenton[2] described the use of oral or parenteral hormones, whereas Dr Hobson[3] summarised 12 years' experience with Hogben tests, and Dr MacDonald and Dr Sharman[4] described a diagnostic method based on the examination of cervical mucus

At the time these letters appeared, I was investigating still another technique for early pregnancy diagnosis and, as I have now completed a series of 100 tests, I should like to present a summary of my results

As Dr Forster stated, the urinary gonadotrophic tests have certain disadvantages, and, for this reason, I have been trying to find a simple, safe, and inexpensive method for diagnosing early pregnancy in general practice In other countries the use of cholinergic drugs such as neostigmine ('Prostigmin') and pyridostigmine ('Mestinon') has had considerable vogue The original method consisted in giving an intramuscular injection of one of these drugs on three consecutive days, and, if the patient was not pregnant, menstruation was said to take place within 72 hours of the last injection For a general practitioner, the need to use the drug by injection was a disadvantage of this method. In 1956, however, Bartolomei and Mincato[5] reported a series of 47 patients with amenorrhœa in whom pyridostigmine (180 mg daily by mouth) was used as a pregnancy test, with accurate results in all except 2 patients

I have now carried out a trial with oral pyridostigmine in 100 consecutive cases of amenorrhœa seen in my practice The age-distribution of the patients and the duration of amenorrhœa were as follows

Age (years)	*No of cases*	*Amenorrhœa (weeks)*	*No of cases*
16–23	38	0–2	16
24–31	33	3–5	63
32–39	21	6–8	21
40–48	8	—	—
Total	100	Total	100

The dose of pyridostigmine was one tablet (60 mg) three times daily for three consecutive days The test was considered "negative" if the patient menstruated within one week of the last dose The results were

Days after test	1–2	3–4	5–7	*Total*
Menstruated				
Negative' results	47	31	5	83
Failed to menstruate				
'Positive result	—	—	—	17

Of the patients in whom the test was "negative", menstruation appeared normal, in no case was there evidence that a pregnancy had been interrupted, though admittedly this cannot be proved The same is true of pregnancy tests based on the use of hormones

Of the 17 patients who failed to menstruate, 14 were later shown by follow-up clinical examinations to be pregnant. There were 3 "false positives", 2 were in menopausal patients (aged 45 and 47 respectively) and 1 was in a girl aged 21 with an infantile uterus The test was thus 100% accurate when negative, and 82% accurate when positive, giving an overall accuracy in 100 cases of 97% The only side-effects were complaints of nausea by 1 non-pregnant and 2 pregnant women

The test was thus shown to be simple, accurate, and inexpensive, the basic N H S cost for a course of pyridostigmine tablets for one woman being about 3*s*

CHOLESTERYL ESTER FATTY ACIDS IN ATHEROMA AND PLASMA

SIR,—Reading again Dr Sinclair's explanation[1] of the controversy concerning the relative deficiency of essential fatty acids (E F A) and the data of the analyses of atheromatous plaques, I should like to suggest a second possibility

The E F A. after having passed the intestinal wall will readily esterify "available" cholesterol, which is known to have a great affinity for unsaturated fatty acids Cholesterol synthesis occurs in many organs If the organ E F A content is too low, the possibility exists that less cholesterol than "normal" is esterified, or that esterification occurs with unusual fatty acids As soon as contact takes place with the newly absorbed E.F.A. in the blood or chyle (whether free or not), the energetically more stable esters can be formed

The physiological "normal" esters must be assumed to be the more stable, though there may be others, such as those mentioned by Dr Sinclair, with an equal stability The resulting esterification of free cholesterol and/or exchange of fatty acids are extracellular processes, the latter could concern phospholipids as well The excess of blood-lipids deposited in the vessel walls will then have an appreciable E F A content, which *will decrease significantly only* when E F A. deficiency is considerable

As a consequence of the extracellular "abuse" of E F.A. only little—and apparently often too little—is left for intracellular use, which means that cholesterol turnover, and breakdown especially, are inhibited (among other intracellular activities) Perhaps it is better to say are inhibited further, since there was already an intracellular shortage of E.F.A. Only by supplying large amounts of E F A can this vicious circle be broken and intracellular activity speeded up to normal, thus removing cholesterol, lowering serum-cholesterol, &c.

That increase of cholesterol turnover and removal follows E F A administration has lately been demonstrated[2–4] Tissue E F A analysis, especially of liver, may help in solving the problem.

A further complicating factor could be found in the observations that fat-free and E F A-deficient diets cause an increase in trienoic content of storage fat,[5] egg-yolk fats and phospholipids,[6] rat mitochondria and microsomes,[7] rat heart and testis fatty acids,[8] together with a decrease in dienoic acids This trienoic was suggested to be partially hydrogenated arachidonate[9] On supplying the polyunsaturated fatty acids (corn oil), trienoic contents decreased and dienoic increased again[5 6] (It is but a step to speculate on a connection with the observation of Keys et al ,[10] who found an increase in serum-cholesterol in man after oral ingestion of arachidonic acid)

B.M A OR A.M.B ?

SIR,—We wholeheartedly support the opinion in your leading article of March 5 that the profession needs an " association of medical bodies ", both to give the various branches of medicine balanced representation and to develop a collective responsibility above that of sectional interests

You rightly point out that the British Medical Association is widely regarded as primarily representing general practitioners, even though they are a minority of its total membership (20,000 out of 74,000) We do feel, however, that the policy of the B M.A does not always truly represent even the conflicting interests within general practice, and in particular those between large-list and small-list practitioners and between principals and assistants It is the lack of overall satisfactory representation for many in the profession that has led to the appearance of special groups within the B M.A , and, as in our case, of independent bodies, to represent minority sections

Machinery to facilitate an exchange of views by representatives from the various sections of the profession might help towards a solution of some existing problems (e g , improving the prospects for registrars and senior registrars) It might also lead ultimately to a confederation of the different medical bodies, to the advantage of the profession as a whole and the future of the Health Service The first step, however, presents a major difficulty

BRETYLIUM TOSYLATE IN THE TREATMENT OF HYPERTENSION

SIR,—Dr Evanson and Dr Sears (March 5) referred to " unexplained exertional dyspnœa " in patients on bretylium tosylate, and Turner and Lowther (Feb 13) noted " dizziness not due to postural hypotension " We feel that both these may be due to exertional hypotension which we have noted in a number of patients on the drug

A fall in blood-pressure on exertion has been previously observed with hexamethonium,[1] and with guanethidine [2] Our experience in the use of bretylium has shown that this phenomenon is of considerable clinical importance and may be a bar to satisfactory control of blood-pressure in some patients

Of 112 patients receiving bretylium, 19 have had symptoms on exertion sufficient to cause some disability The symptoms complained of were faintness, giddiness, or dizziness (11 cases), muscular weakness (4), and breathlessness (4) 4 of these patients have been so disabled that they were unable to carry on their work or normal household duties or climb up one flight of stairs without resting 1 patient was even unable to dress himself

We have measured the blood-pressure before and immediately after exertion in 13 of these patients 11 of them showed falls of pressure ranging from 15/25 to 160/80 (mean fall 59/47 mm. Hg) The exertion consisted of walking slowly upstairs until the symptoms occurred, usually only one flight was necessary Of 6 control patients who were taking bretylium without exertional symptoms, only 1 showed a fall in pressure after four flights of stairs

In 4 of these patients a considerable exertional fall of blood-pressure occurred in the absence of any postural fall Blood-pressure readings from the two most striking cases were (*a*) lying B P 225/165, standing 210/170, after one flight of stairs 120/90, (*b*) lying 240/140, standing 250/150, after one flight of stairs 90/70

The mechanism of this effect is as yet obscure 2 patients who had exertional hypotension on bretylium showed the same effect on guanethidine We suggest that it may be due to a failure to increase the cardiac output with exercise

PULMONARY DIFFUSING CAPACITY

SIR,—The letters (Feb 6) from Dr McNeill and Dr Ogilvie raise two points in the technique of the single-breath method of measuring the pulmonary diffusing capacity (D_L)—first, the size of sample collected, and second, the time of collection

Dr McNeill says that in modifying the single-breath test for measuring the D_L we have made an erroneous assumption about the way in which the expired air is usually collected In fact, no such assumption was made, for it is clear from the literature [1–6] that there is considerable uncertainty as to which portion and how much of the expired gas is collected.

We started by accepting the fact observed and discussed by Ogilvie, Forster, and others [1,4,7] that the diffusing capacity varies with the length of breath-holding We offered theoretical and experimental evidence that such variations in normal subjects are due to experimental technique and not to regional inequality of lung function

Dr McNeill's statement that only 300 ml is required suggests that he is confusing the volume needed for analysis of the gas with that actually collected, for it is clear from their section on " method ", that Ogilvie et al [4] collected a much bigger sample They state that " all of this expiration except the first litre is collected in a bag", and Forster et al [1] that the subject "rapidly expired to residual volume turning (the) tap to collect the sample after a litre or more of gas had been expired " Dr Ogilvie in his letter says that, " providing that the subject is told to expire with all his might, he will add little to the sample after 2 or 3 seconds " We conclude that, with the exception of the first rejected litre, the greater part of the expirate, almost to residual volume, is sampled A simple calculation shows that in order to sample only 300 ml in the early part of a maximum expiration of a normal subject would require an ability to manipulate the tap twice within approximately $^1/_6$ second.

That samples of more than 300 ml were actually used by Forster et al is confirmed by our finding that when a large sample (2 6 litres) is collected, our results for the effect of changing the breath-holding time were superimposable (after allowing for an 8% difference in diffusing capacity) on those published by Forster However, when we used a sample of 85 ml virtually no variation with breath-holding time was observed Thus we conclude that large samples must have been used in Forster's original experiments

Dr Ogilvie also states that our correction to his data would result in a change of only about 5% If the sampling-times are 1–2 seconds, such alterations would approximately be 5–10% at a 10-second breath-holding time, but 10–20% for a 5-second breath-holding time, which is often as much as disabled subjects can do In addition, if there is a considerable change in alveolar volume, attendant upon either a large or a late sample, there is an error due to this which is not corrected by the simple allowance for sampling-time, so that the total error may be much larger than the 5% suggested

In patients with obstructive disease the effect of alveolar volume change may be small, but as the sampling-time in these cases may be as long as 4 seconds, the correction for this time becomes even more important, especially as such subjects are also those who are often unable to hold their breath for more than a few seconds Such short breath-holding times may also apply when the test is used on normal subjects when exercising

---

[1] Forster, R. E , Fowler, W S Bates, D V , Van Lingen, B *J clin Invest* 1954, 33, 1135

[2] Forster, R E , Cohn, J E , Briscoe, W A S , Blakemore, W S , Riley, R. L *ibid* 1955, 34, 1417

[3] Bates, D V , Pearce, J F *J Physiol* 1956, 132, 232

[4] Ogilvie, C M , Forster, R E , Blakemore, W S , Morton, J W *J clin Invest* 1957, 36, 1

[7] Forster, R E *Physiol Rev* 1957, 37, 391

We are, therefore, convinced that it is necessary to use small early samples (<1 litre) when allowance for the time of sampling can be made In this way a considerable improvement in both repeatability and validity is achieved The summation of such errors may be sufficient to explain a situation which has recently come to our notice, in which a normal man was tested in one laboratory and found to have well over 100% predicted value Tested in another laboratory a few days later, he was told that his value, alas, was only 60% of expected

PRIVATE PATIENTS IN THE NATIONAL SCHEME

SIR,—I have followed with great interest the lengthy correspondence on this subject There are several points which require answering

Why do patients who are entitled to treatment under the terms of the National Health Service seek private treatment at all? In my view it is neither the social aspect nor the so-called snob value but the time factor which counts

My own practice has been entirely amongst the elderly who come to me because I am prepared to spend the necessary time on them, and listen patiently to what they have to say When these same people go to their N H S doctor's surgery he is probably busy and they have to wait their turn When it does come they have to collect themselves and walk into the doctor's presence—a slow business Then they have to explain what they have come about and receive attention all this takes time in a busy surgery This type of patient, I believe, forms the majority of private patients these days

It will be a bad day for British medicine when private practice ceases to exist, everything should be done to encourage it Please do not let us hear any more of its social or snob value

Worthing

HAROLD LEESON

OVERDOSAGE OF PHENELZINE SULPHATE

SIR,—Dr Sclare and Dr Atkinson (Jan 30) raise the question of overdosage of thymoleptic drugs and outpatient regulation of their administration

An admittedly limited experience of these drugs gives the impression that whether they should be started on in outpatients depends on the presence of a premorbid stable personality structure and the absence of an underlying delusional system. It seems that where the depressive affect or anergy is primary then outpatient treatment is desirable, depending of course on the severity of symptoms Secondary mild delusional ideas or hypochondriasis would obviously not contraindicate this, if treatment is successful they will disappear with the primary symptoms If these two conditions are not fulfilled, however, it seems prudent to admit the patient to hospital to determine the maintenance dose and feasibility of continued treatment, since these drugs, contrary to a recent statement[1] that they appeared to have "little significant action beyond placebo effect", are indeed powerful in action in many patients and can produce startling not to say alarming results

The following case illustrates this point

A man of 24 was admitted to this hospital some two and a half years ago in acute mania after taking iproniazid ('Marsilid') five tablets a day (admittedly beyond the manufacturers' recommended dose) He was diagnosed as "chronic undifferentiated schizophrenia", the main symptoms of which were extreme inhibition, inability to converse with others, particularly women, and undefined ideas of reference and the feeling that people were laughing at him. He was apt to spend a considerable amount of time standing awkwardly on the edge of groups of fellow students unable to join in and with his arms stretched out straight and hands clenched After taking iproniazid he became progressively less inhibited, and his social contacts became more and more self-assured until eventually he tried to pass a cheque for $70,000 in a local hotel, which brought him to public attention before his admission to hospital as an emergency

He was discharged after eighteen months apparently somewhat improved, but he was readmitted some six months later because he "couldn't talk to women" and would spend hours standing pondering over this problem. On the second admission it was decided to try him on imipramine ('Tofranil') to see whether the dosage of the drug could be adjusted to enable him to converse easily with his fellows and avoid hypomania, but this was not easy When it was noticed that he was a shade too cheerful the dose was reduced from six tablets daily to three—but too late Next morning he had written two letters to State senators demanding legislation on the management of mental hospitals, and he had to be withdrawn from his employment in the hospital canteen. He quickly quietened down after withdrawal of the drug and administration of chlorpromazine A further attempt may be made later, on one tablet a day

Another patient whose main symptoms seemed to be those of depression quickly had his original paranoid psychosis reactivated by imipramine On withdrawal of the drug, however, he soon ceased expressing his delusional ideas and a change to nialamide ('Niamid') seemed to remove the depression without provoking the underlying paranoid ideation.

A SIMPLE DIAGNOSTIC TEST IN THE STEIN-LEVENTHAL SYNDROME

SIR,—The clinical diagnosis of the Stein-Leventhal syndrome is not easy, and investigation by culdoscopy and/or radiography with retrorectal gas insufflation is trying for patients and cannot be performed in small centres, where it would also be impossible to make difficult hormonal assays We want to indicate to your readers the practical value of an easy test which, we think, might help in the recognition of the Stein-Leventhal syndrome in those women with hirsutism, conspicuous menstrual disturbances (usually amenorrhœa), occasional sterility, and normal or slightly increased urinary 17-ketosteroids—that is, those cases which could be successfully treated with a wedge resection of the polycystic ovaries

The test can be performed as follows (*a*) careful collection of the urine during four consecutive days, (*b*) on the morning and in the evening of the 3rd day the patients receive by intramuscular injection 25 mg of progesterone in oil, (*c*) assay of the 17-ketosteroids is performed on the mixed urine of days 1-2 and days 3-4

In normal women the injection of this amount of progesterone never increases urinary 17-ketosteroids On the other hand, in those women with hirsutism and normal or slightly elevated urinary 17-ketosteroids the same treatment can be followed by two completely different results

(1) In one group the test is "negative" (the urinary 17-ketosteroids do not increase after the two injections of progesterone), as in normal women in over 90% of women in this group menstruation is normal

(2) In another group the test is "positive" (the urinary 17-ketosteroids increase by 2-10 mg in the 48 hours after the two injections of progesterone), almost all these women have conspicuous menstrual disturbances (usually periods of amenorrhœa)

Since in all the women with hirsutism, conspicuous menstrual disturbances, normal or slightly increased urinary 17-ketosteroids, and a "positive" test, the administration of cortisone has been without effect and we have been able to exclude any other cause of the syndrome, we have supposed that these women might have the Stein-Leventhal syndrome

Three such women have already been operated on and in each our presumed diagnosis of Stein-Leventhal syndrome was correct All of them have had good results after wedge resection of the ovaries Whenever it is impossible to perform more difficult and/or more complicated examinations, we therefore think that an increase of urinary 17-ketosteroids after injection of progesterone (" positive " test) might be sufficient criterion for a diagnosis of Stein-Leventhal syndrome in those women with hirsutism, conspicuous menstrual disturbances, occasional sterility, and normal or slightly elevated urinary 17-ketosteroids

V PATRONO
G NICOLOSI

BRONCHOGRAPHY

SIR,—I agree with Dr Smith and his colleagues (March 5) that a lot of heavy weather is made over bronchography, and their method is simple and effective. An equally simple and quick method is that with the Elaine Field needle, using the cricothyroid route

This needle is, in effect, a small curved cannula with a short-bevel pointed end and a flush-fitting stylet which is mounted on a handle for ease of insertion It was originally developed for children, but adult sizes are easily obtainable After insertion, the cannula is tied in position with tapes, which obviates two snags of the ordinary cricothyroid method —i.e., having to hold the needle carefully so that it stays in the right place, and having to reinsert it if both sides are being done at one session The proximal end of the cannula is 'Record'-fitting to take the bronchogram syringe, which can be disconnected as soon as the right side has been done, and reconnected to do the left after the first lot of films have been taken

Premedication is not normally necessary and 1 ml of 2% lignocaine through the cricothyroid membrane via a no 12 needle should suffice to anæsthetise the skin and bronchial tree (A second 1 ml may be advisable in bronchitic patients with a good deal of sputum) The method is very satisfactory for outpatients

J B WILKINSON

AUTOIMMUNE HÆMOLYTIC ANÆMIA WITH ACUTE RENAL FAILURE DUE TO PHENACETIN AND P.A.S

SIR,—Following the paper in your issue of Jan 2 by Dr Barbara MacGibbon and her colleagues, I should like to report another case [1] of sensitivity to P A S

A 50-year-old man had been treated for several years for pulmonary tuberculosis associated with renal diabetes During 1956 he received 15 intravenous injections of P.A.S (15 g daily) The 14th and 15th injections were followed by fever Two years later 12 injections were given. The last 3 injections were ill tolerated (general malaise, vomiting, and fever) Three months later another injection had to be stopped because of severe shock. At no time were signs of hæmolysis observed (no icterus, no dark urine, no anuria or even oliguria) No immediate hæmorrhagic syndrome developed.

The blood was examined 39 days after the last P A S injection The serum contained an " allergic " antibody capable of agglutinating all compatible red cells, all leucocytes, and platelets of the same blood, but only in the presence of P A.S (0 05 g per 100 ml final concentration) The average titre was $^{1}/_{128}$ for red cells, and $^{1}/_{16}$ for leucocytes and platelets The reaction was stronger at 37° C than at 15° C or 4° C No hæmolysis of normal or trypsinised red cells could be demonstrated with fresh serum or with inactivated serum samples to which fresh human serum had been added as a source of complement, in neutral or acid medium This antibody was still active after heating at 56° C for 20 minutes, but was destroyed by heating at 70° C for 10 minutes The reaction was inhibited by E.D T.A (disodium sequestrene) The action on platelets could also be demonstrated by the inhibition of clot retraction The antibody could be absorbed and eluted either on red cells and leucocytes or platelets

The reaction was equally positive with, instead of P.A.S , 3-amino-sodium salicylate, 5-amino-sodium salicylate, *p*-amino sodium benzoate, sodium salicylate, sodium gentisate, methoxy-2-sodium benzoate, nitro-3-sodium salicylate, and nitro-5-sodium salicylate It was negative with sodium benzoate, sodium phthalate, *p*-sulpho-sodium salicylate, sodium acetyl salicylate, sodium *p*-amino hippurate, *m*-amino-phenol, and phenacetin

The antibody was not neutralised by the addition of P A.S to the serum nor could it be removed by red cells alone

This case is remarkable because this strong antibody did not provoke clinical hæmolytic anæmia or a hæmorrhagic syndrome although it was active in both red cells and platelets

LUNG CANCER AND TOBACCO MOSAIC VIRUS

SIR,—In the search for carcinogens in tobacco smoke there appears to be little research activity in relation to the presence of active tobacco mosaic virus (T.M V) in the finished tobacco as found in cigarettes and pipe tobacco This virus resists the processes of tobacco manufacture, remains infective for plants,[1] and can be demonstrated serologically in tobacco offal [2]

As a high-molecular-weight protein, it might not be expected that T.M.V would be carried through in tobacco smoke, but it would be present for ingestion on contact with tobacco (a frequent occurrence in the cigarette-smoker but less common in the pipe-smoker) The induction of lung cancer by an ingested or not predominantly inhaled agent would also be an explanation of the apparent (but not universal) finding in lung-cancer/smoking statistics that inhalers are no worse off than non-inhalers [3] In these circumstances the cigarette would really function as a man-made vector, perhaps incorporating the correct chemical and temperature changes for the virus at the same time

The content of ribonucleic acid (R.N.A.) in T.M.V is approximately 5%,[4] and it is interesting that the other virus which has been suggested as a possible ætiologic agent in lung cancer (influenza virus) also has its nucleic acid in the R.N.A. form. The fundamental role of the nucleic-acid molecule in cell metabolism, which is the subject of so much current interest, is surely worth studying in relation to the R.N.A. of T.M V in tobacco If T.M V is involved in the ætiology of lung cancer, one might consider that, being a plant and not an animal virus, long exposure would be necessary for the incubation of lung cancer

The fact that many types of plant virus must be eaten regularly without causing apparent ill-effect (from tomatoes, vegetables, &c) would suggest that T.M.V may have to be modified to attain pathogenicity for animals The combustion processes in the cigarette might provide such a media for modifying the T.M.V and it would be interesting to know whether the R.N.A is liberated in this way from its protein or whether it is itself modified in the smoking process

T.M V must occupy a unique position in biology as the only virus likely to be brought into contact with man at a time when it is being subjected to a considerable temperature gradient [5,6] near the burning cigarette end, as well as complex chemical processes [7] going on around it or near to it in the burning of tobacco Many possible changes could occur in the virus and the R.N.A in the smoking process if one compares the changes in the influenza virus when exposed to heat [8]

2 Imperial Tobacco Co Personal communication, 1959
3 Doll, R., Hill, A. B *Brit med J* 1950 ii, 739
4 Smith, K. M. Recent Advances in the Study of Plant Viruses, p 144 London, 1951
5 Harlow, E. S *Science*, 1955, 123, 226
6 Greene, C. R. *ibid* p 227
7 Clemo, G R. *J R Soc. Hlth*, 1959, 79, 74
8 Burnet, M. Enzyme Antigens and Virus Cambridge, 1958

Separation or modification of the protein from the R.N A or modification of the virus protein would not seem unlikely in these circumstances If the virus R N A is involved then what we are asking is how long does it take virus R.N.A or virus protein, modified perhaps in the smoking process, to upset the normal R N A /protein mechanism in the lung cell? Certainly many possible changes in the R.N A /protein mechanism are possible Could bronchial mucosa be selectively sensitive to this change?

The experience of tobacco workers [9, 10] may not be very relevant to the problem unless they smoke, since the smoker gets much " closer " to the tobacco for ingestion than anyone else, and smoking the virus may be different from working with it

Other factors seem relevant The ability of plant viruses to multiply in non-plant tissue, e g insects—is known [11, 12] Also the refractoriness (resistance to heat and formaldehyde) of the agent responsible for an animal disease (scrapie in sheep) shows that it is possibly another example of an unidentifiable transmissible agent, apparently more akin to some plant viruses than to animal viruses [13] An insect-virus also contains R.N A [14] Viruses involved in human disease have been shown to contain R.N A (influenza, poliomyelitis)—i e, the ability of plant viruses to multiply outside the plant tissues is accepted, the agent of another animal disease seems more to resemble a plant-type virus than an animal-type virus, and R.N A is present in virus pathogens of insects and man, particularly in a virus suggested as a possible ætiologic agent in lung cancer (influenza) Finally the D N A changes in the nuclei of influenza virus infected cells have been reported as implicating D N A also in the multiplication of an R N A virus [15] Similar nuclear and D N A changes in poliomyelitis infected cells have been reported.[16] Perhaps attention should be focused on these two active methods of introducing virus R N A to the human lung

The effect of injected " labelled " T M V in the mouse has been studied by Erickson et al.,[17] who demonstrated T M V uptake in the mitochondria of liver cells, though they did not show intracellular localisation of the virus particles except within the vacuoles of Kupffer cells They attribute their failure to demonstrate the T M V in the nuclei to deficiencies in their technique

This possibility of plant-virus involvement in obscure human disease may seem somewhat remote, but the manner of induction of tumour formation by viruses in plants and animals appears to be similar [18] That the virus (T M V) is not " like " animal viruses (i e, is a simpler organism) may be more in support of the theory than against it since we would perhaps anticipate a different R.N.A /protein mechanism which is not quite right for the animal (lung) cell The recent theory of Commoner [19] on the lengthwise replication of T M V and its apparent dependence on protein participation to do so may be relevant Neither are we looking for an acute illness, long-term possibilities would have to be considered and a mechanism which did not destroy the lung cell

The possible pathogenetic role for animals of T M V and other plant viruses in tobacco should be investigated, at least to exclude their possible involvement in cancer of the lung It would be intriguing if the virus which has probably received more study than any other was concerned in the ætiology of lung cancer

A MEMORIAL TO THE LATE DR. BERNARD JOHNSON

SIR,—The sudden and unexpected death of Bernard Johnson in May, 1959, left the Board of the Faculty of Anæsthetists with a great sense of loss which became more apparent as the scope of the work he undertook on its behalf came to light Many of the present activities of the Faculty of Anæsthetists were initiated by Bernard Johnson and it was his imagination and persistence which carried them through to completion These include the establishment of the research department, which was not only his idea but for which he collected the funds almost singlehanded, the Faculty scientific meetings, the provision of lecture courses, and the training of postgraduate students

Many of his friends have expressed the wish to have an opportunity to contribute to a memorial and a committee has been set up to this end We hope to collect £6000, and it is proposed that this will be devoted to the foundation of a lecture, the provision of a plaque costing approximately £200 to be placed in the Research Department of Anæsthetics at the Royal College of Surgeons, and to provide for a Faculty adviser in postgraduate studies, a function of the Faculty which was very near to Bernard Johnson's heart

All those friends and colleagues of Bernard Johnson who would like to be associated with this memorial are invited to send their contributions to the Dean of the Faculty of Anæsthetists, Royal College of Surgeons of England, Lincoln's Inn Fields, London W C 2 Cheques should be made payable to The Faculty of Anæsthetists

Parliament

The Supplementary Estimate

THE Ministry of Health has asked for a supplementary estimate of just over £$23^{1}/_{2}$ million [1] This, Mr DEREK WALKER-SMITH explained to the Committee of Ways and Means on March 14, contained three main items Much the largest was £13 8 million for advances made to hospitals on revenue account, of this over 60% was needed to meet pay increases, including almost £11 million for nurses and midwives which brought their pay into line with the relative rewards enjoyed in the community This was at once an act of justice and an act of policy, and he made no apology for it, costly as it was

The second main item, £5,684,000, was for the pharmaceutical services This was due to an increase in the number of prescriptions and to an increase in their average cost, estimated originally as *6s 8d*, but now as about *6s* $10\frac{1}{8}$*d* He had on Jan 29 sent out a special notice, agreed by the General Medical Services Committee, calling attention to the importance of limiting quantities prescribed Cost investigation in 1955 had established that profits for unbranded standard drugs were not unreasonable, and there was no reason to suppose that the position had changed since then. For proprietary preparations there was an agreement for price-regulation This was now in the third year of its trial period, which ended in June, and was being reviewed There had, over the past few years, been major advances in drugs which flowed from a substantial research programme conducted by the industry at its own expense, estimated at about £5 million last year He thought that our policy must have regard to the desirability of obtaining drugs for the National Health Service at reasonable prices and of providing conditions favourable to further research and development in the industry There had been a pilot inquiry into the payment of chemists, and a large-scale inquiry covering a range of nearly 1000 standard drugs was now being made The results of the first six months of the inquiry had become available on Dec. 1 and, after consultation with chemists, certain price adjustments had now been introduced

---

[1] *Lancet*, Feb 13, 1960, p 395

The third main item in the Estimate was £1,600,000 for the purchase of poliomyelitis vaccine The tragic death of an international footballer had made a more vivid impact on the minds of young people than any medical or ministerial exhortation, and by the end of the year the number of young people accepting vaccination was just under 2$^1/_2$ million 8$^1/_2$ million children had also accepted vaccination, and more than 6$^1/_2$ million people—children and adults—had had a third injection

Dr **Edith Summerskill** was dissatisfied with the rising cost of the pharmaceutical services and reminded the Minister that the Comptroller and Auditor-General shared her dissatisfaction[2] In 1956 proprietary drugs accounted for 36% of the drug bill The Minister had not mentioned the present proportion, but she believed that it now stood at 70% The majority fell into categories classified by the Cohen Committee as not therapeutically superior to standard preparations Cheaper standard drugs would not only be equally effective, but would not have the unfortunate side-effects of some proprietary drugs which had never had adequate clinical control in this country A leading article in the *British Medical Journal*[3] drew attention to a drug shown to be carcinogenic in animals, which was still being prescribed to people although it was not being advertised.

The Auditor-General, she continued, was doubtful about the effectiveness of the voluntary price-regulation scheme, on which the Minister still appeared to rely The revelations at the hearings of the United States Senate Anti-Trust and Monopoly Subcommittee on the price of drugs had shocked public opinion in America, and these firms for the most part had established themselves in Britain and were adopting the same business methods here

In conclusion she asked if the time had not come to examine the prescribing of the specialists Some of them were asked by the drug houses, in return for suitable remuneration, to test preparations It was remarkable how a consultant then became prejudiced in favour of one firm. The drug bill of the hospitals had become so high that it was decided to prescribe only for one month for outpatients and then let the general practitioner continue on E.C.10

Miss **Edith Pitt**, parliamentary secretary to the Ministry, said that the drug mentioned in the *B.M.J.* leader was subjected to extensive animal tests and, when it appeared safe, was released for clinical use Over the past five years an enormous number of patients had been treated in this way, and, apart from a local staining reaction at the site of injection, no side-effects or toxic reactions had been reported There had been investigations subsequently on animals by other doctors using massive doses—proportionately far higher than those ever likely to be used clinically In any event, this carcinogenicity in animals would not necessarily occur in man, and it remained simply as a warning The doctors had been given this warning in the medical Press, so few could be unaware of it It must be left to the practitioners to assess the benefits and conceivable risks, and to decide for themselves whether to embark on such treatment

The Ministry's information suggested that, for many of the most important drugs, prices in the United States were about twice as great as those charged in Britain by the American subsidiaries The American firms of which Dr Summerskill was so critical helped considerably both in the production of our drugs and in our exports Through their activities our industry had benefited from the very considerable research efforts in the U.S.A. and Switzerland Voluntary price regulation had produced a considerable number of price-reductions—about 300—and during the past two years prices of corticosteroids had been reduced by 30% without prompting

QUESTION TIME

Doctors' and Dentists' Remuneration

Mr L. A. **Pavitt** asked the Minister of Health whether he would fix a date for preliminary general discussions with the medical profession concerning the report of the Royal Commission on Doctors' and Dentists' Remuneration —Mr **Derek Walker-Smith** replied I am not yet ready to propose a date, but I have informed the profession that the Secretary of State for Scotland and I would wish to have such discussions as soon as the Government have completed their initial study of the report.

National Health Service Superannuation

Mr G. **Thomas** asked the Minister of Health what representations he had received from trade unions concerning his unilateral decision to alter the terms of the National Health Service superannuation scheme —Mr **Walker-Smith** replied I have received representations against the proposal to abolish the payment of interest on contributions returned to those who voluntarily leave National Health Service employment, but not against the proposal that the Exchequer should take responsibility for all but a very small part of the actuarial deficit of £80 million I am at present considering these representations

Special Hearing-aids for Children

Mr S. S. **Awbery** asked the Minister if he was aware that children in need of special hearing-aids other than the 'Medresco' are unable to obtain the special types required free under the National Health Service, nor can hospitals supply them to patients nor offer grants towards the cost if purchased privately and if he would take steps to provide special aids, such as bone conductors, free where necessary on the recommendation of an ear, nose, and throat consultant of a local authority —Miss **Edith Pitt** replied There is in the range of medresco hearing-aids a valve-type bone-conduction aid which is obtainable free on the recommendation of a hospital consultant. Commercial aids are not supplied under the hospital service, but in appropriate circumstances a local education authority may provide them without charge through the school health service

Artificial Limbs

Mr L. M. **Lever** asked the Minister if he would indicate the improvements in design and fitting of artificial limbs which have accrued from the work of the Department of Research and Experiment at Roehampton since 1947 —Miss **Pitt** replied As a result of the work of the research department, in conjunction with the manufacturers of artificial limbs, there has been substantial improvement in the fitting, alignment and stability of artificial limbs new types of sockets, corsets and pylons have been introduced the use of new materials has been extended and walking appliances for children have been developed. The design of arms has been improved, and many special arm appliances have been produced. Apart from the work which is done for amputees, appliances for patients with paralysed arms have been developed

Mr **Lever** asked the Minister the average time now taken for major repairs to artificial limbs at Roehampton. Miss **Pitt** Between 3 and 4 months Mr **Lever** asked the Minister the average time now taken to supply an entirely new artificial limb, from the date of first measurement to the date of delivery of the new limb —Miss **Pitt** About 98 days

Cost of Poliomyelitis Vaccination

About £6 million has so far been spent on the purchase of poliomyelitis vaccine for England and Wales and the further cost of supplies for 1960 is estimated at £1 7 million

Obituary

DOUGLAS JAMES CAMPBELL

F R C P E, D P H

Dr D J Campbell, consultant venereologist to the Sheffield and district area and lecturer in venereal diseases in the University of Sheffield, died in the Royal Hospital, Sheffield, on March 6 He was 56 years of age

Douglas Campbell spent much of his early life in Edinburgh He was educated at George Watson's College and the School of Medicine in Edinburgh He was a licentiate in dental surgery but he never practised dentistry, and he qualified L R C P E in 1927 After holding house-physician and house-surgeon posts at the Royal Infirmary, he became senior clinical assistant in the department for venereal diseases in the hospital in 1929 He took the D P H in 1931, and between 1932 and 1937 he was V D officer and pathologist for Southampton and consultant in V D to the Royal Hants and Southampton Hospital In 1937 he became consultant venereologist to the city of Lincoln and Holland County Council, V D officer and pathologist to Grimsby County Council, and venereologist and dermatologist to the Grimsby Hospitals From 1939 to 1944 he served as a specialist at headquarters of the Aldershot and South-Eastern Commands and at the Connaught Military Hospital, Aldershot He also served overseas as adviser in venereology to Allied Forces Headquarters, North Africa, and to 21 Army Group of the British Liberation Army He held the rank of lieut-colonel and was awarded the territorial decoration

After the war he returned to Grimsby, and when the National Health Service was started he became consultant venereologist and moved in 1949 to take charge of the V D departments and clinics in the Sheffield district He was appointed lecturer and clinical teacher in 1950

C H S-H writes

"Campbell's early days in Sheffield were hampered by inadequate premises, lack of beds, and at first difficulties in obtaining enough clinical material for the instruction of undergraduates He set to work with zeal, however, and built up a first-class service for the treatment of patients and for teaching Perhaps it was the feeling that the worthwhileness of his medical work was not always recognised that led him to pursue many activities outside medicine Thus he was a keen rotarian and member of the Edinburgh University association in Sheffield He was a governor of Epsom College He was also a member of the Central Consultants and Specialists Committee of the British Medical Association His status in his own specialty was recognised by his presidency of the Medical Society for the Study of Venereal Diseases"

Dr Campbell leaves a widow and two sons

JOHN RODERICK BULMAN

M B Edin

Dr Bulman, who died in the General Hospital, Hereford, on Feb 17, was the senior general practitioner of the city

He was born in Kelso in 1886 and qualified from the University of Edinburgh in 1913 After holding a house-appointment in Edinburgh Royal Infirmary he served throughout the war in the R A M C On demobilisation he joined the late Dr Thompson of Hereford in partnership He retired two years ago He leaves a widow, four sons, and a daughter

H W-S writes "At the end of the late war, Dr Bulman was instrumental in reviving the almost moribund Hereford Medical Society which is now a flourishing institution, and last year the members presented him with a silver salver For some years he was also a member of the Hereford city council His vigorous and kindly personality attracted a host of friends and he was held in universal honour and esteem"

Dr. S. A HENRY

T L D writes

"Your obituary notice of S A Henry, which so sensitively conveys his terrier-like powers, both the delight and despair of his friends, omits any reference to Sir Thomas Legge's book *Industrial Maladies* Though this book was possibly in draft before Legge's death, Henry's contribution in seeing it through the press was undoubtedly big Legge was a great man and Henry an inspired admirer Whatever was the contribution of each, the result was a medical classic To mention Henry's share does not detract from Legge's greatness On the fly-leaf of the book is a quotation ascribed to Thomas Fuller 'He who cures a disease may be the skillfullest, but he who prevents it is the safest physician' Some years ago, having failed to trace the quotation in the writings of either of the two Thomas Fullers, I wrote to Henry to ask him the source For once it seemed that Henry's terrier-like qualities were beaten, and he had to admit that he did not know I have often wondered whether the quotation (so perfect a description of preventive medicine) might not have had its origin with Legge or Henry If any reader can trace the quotation I am sure no-one would be more delighted than Henry"

Notes and News

STERILE SUPPLIES IN HOSPITAL

For some years the Sunderland Royal Infirmary has made studies on routine surgical dressings and minor surgical procedures in its medical and surgical wards, its theatres, and its outpatient departments With the publication of the Nuffield Provincial Hospitals Trust's report[1] on sterilisation practice in six hospitals, and others such as that of Darmady et al,[2] this work received new emphasis A team consisting of the group pathologist, two surgeons, and four ward sisters collaborated to set up a central sterilisation service for four wards—three medical and one surgical. This service has been limited in its resources but has already proved its worth by showing that ward sterilisers become unnecessary, that routine dressing of wounds and preparation of trolleys for such procedures as lumbar puncture can be simplified, and that the time taken over these nursing practices can be materially shortened The impression has been gained that secondary contamination of surgical wounds has been significantly reduced

The central supply service has approached its task with the attitude " You tell us what you need, and we will provide it." The system has proved acceptable in practice and has led to a standardisation of technique which has its economic appeal. It is intended to extend it to the other wards, and to such parts of the theatre work, and casualty department and outpatient clinics, as are likely to profit from it This raises many more administrative and logistic problems than have been met in the pilot scheme

The Nuffield Provincial Hospitals Trust has shown its interest not only by providing the advice and experience of its working party on hospital sterilisation but also by a grant[3] of £10,000 towards improving the accommodation and increasing the equipment.

PART-TIME RESEARCH

Much has been said about the need for posts enabling a consultant in the National Health Service to divide his time between research and hospital practice, and a few such posts have been created To encourage this combination of clinical work with investigation, the Royal College of Physicians of London is now advertising some of its research fellowships in such a way that they could be held by part-time consultants In our advertisement columns this week it invites applications for a Joseph Senior White fellowship, which might be extended up to five years

THE STUDENT AND THE CURRICULUM

The British Medical Students' Association has published reports on the teaching of social medicine and of psychiatry and psychological medicine[4] Both reports were prepared by Dr Roderick MacSween, who was education officer of the Association in 1958–59

The Association recommends that in all medical schools the students' curriculum should include a course on *social medicine* which should cover aspects of immediate concern to the newly qualified doctor, such as medical sociology, epidemiology, health administration, and the health and welfare services Visits to factories, kitchens, special clinics, and patients' homes should be included The importance of disease, not only to the individual but to the community as a whole should be stressed The Association would not like to see social medicine included as a subject in the final examination, but suggests that a combined examination in social medicine and infectious diseases might be part of a professional examination

In the report on *psychiatry and psychological medicine* the Association recommends that normal psychology should be taught alongside the preclinical course in anatomy and physiology Psychiatry should form an integral part of the clinical course in medicine Students should spend more time at outpatient clinics and on ward-rounds in mental hospitals and units The emphasis should be on the commonest mental disorders in general practice and in general hospital wards The Association would like to see the student taught some psychotherapy, and residence or a period of clinical clerking should be compulsory An examination in psychology should become an obligatory part of the 2nd M B in physiology, and an examination in psychiatry of the final examination in medicine Psychiatrists should be included among the examiners in the final examination in medicine Many of these recommendations are embodied in the course in psychology and psychiatry lately introduced at Sheffield University

---

University of Cambridge

On March 5 the following degrees were conferred

M D—A G Ackerley, J C Barker
M Chir—*I S M Jones
M B—*N A Atalla, *P J F Baskett, *Simon Harcourt-Webster
* By proxy

University of Aberdeen

The honorary degree of LL D is to be conferred on Lady Baird, chairman of the North-Eastern Regional Hospital Board, Sir David Campbell, regius professor of materia medica at the University, and Dr R S Aitken, vice-chancellor of the University of Birmingham.

Royal College of Physicians of London

Dr D Evan Bedford will give the Lumleian lectures on Tuesday and Thursday, April 5 and 7, at 5 P M at the college, Pall Mall East, S W 1 He will speak on disorders of the pulmonary circulation

Royal College of Surgeons of England

Faculty of Anæsthetists—The following have been elected to the Board of Faculty

Dr M. D Nosworthy, Dr J A Lee, Dr G Jackson Rees, Dr W D Wylie, representing the fellows, Dr R. V Sturton, representing the members

A diploma of fellowship has been granted to I M Hallack.

British Medical Association

The annual meeting is to be held in New Zealand next year, and Mr Douglas Robb, surgeon to the Greenlane Hospital, Auckland, and pro-chancellor of the University of Auckland, has been elected president of the Association for 1961-62

Research on Bone Sarcoma

The Medical Research Council invite applications for a Nathan research fellowship for the evaluation of different forms of therapy in bone sarcoma Further particulars will be found in our advertisement columns

Medical Administration

The Nuffield Provincial Hospitals Trust is offering six grants (of £500 each) to medical or non-medical graduates who wish to take the course for the diploma in medical services administration in the University of Edinburgh Further particulars will be found in our advertisement columns

Refresher Course in Psychological Medicine

Eleven weekly lecture-seminars for general practitioners have been arranged under the auspices of the British Postgraduate Medical Federation by the department of psychological medicine at the Royal Free Hospital The course will start on April 27 or 28 Further particulars may be had from Dr S W Hardwick, Royal Free Hospital, Gray's Inn Road, London, W C 1

Human Relationships in the Care of Mother and Baby

A conference on this subject will be held by the Royal College of Midwives from March 28 to April 1, at St. Anne's College, Oxford The speakers will include Sir John Charles, Dr Eleanor Mears, Dr P E Polani, Dr John Apley, Dr D L Kerr, Dr David Morris, Mr P J Huntingford, Mrs C L Beynon, Dr Mavis Gunther, Dr S A. MacKeith, Dr A K Graf, Dr T E Oppe, and Dr M. E T Mackenzie Further particulars may be had from the education office of the college, 15, Mansfield Street, London, W 1

[2] Darmady, E M , Hughes, K E A , Jones, J D , Verdon, P *Lancet*, 1959, i, 622

[3] *Times*, March 7, 1960

[4] Obtainable from the B M.S.A , B.M.A House Tavistock Square, London, W C 1

International Congress on Proctology

This conference will be held in Rome on May 13 and 14 Further particulars may be had from the executive secretary, Dr G B E Simonetti, Via S Raffaele 3, Milan, Italy

International Congress of Internal Medicine

This congress will be held from Aug 24 to 27, in Basle The principal subjects of the congress will be pathogenesis and treatment of œdema and clinical uses of enzymes Further particulars may be had from the secretary of the congress, Prof H Ludwig, Steinentorstrasse 13, Basle 10, Switzerland

Institution of Hospital Engineers

On Saturday, April 9, at 2 30 P M at Westminster Medical School, Horseferry Road, London, S W 1, Dr L R West will give the Sandford Premium lecture His subject will be engineering principles in medicine

Institute of Accident Surgery

On Monday, April 25, at 5 30 P M, in the department of anatomy of the University of Birmingham, Lieut -General Sir Alexander Drummond, director-general of Army Medical Services, will give the inaugural Ruscoe Clarke lecture He will speak on the care of the injured

Hospital Board Chairmen

The Minister of Health has made the following new appointments of chairmen of hospital boards

Royal Hospital of St Bartholomew, Mr M W Perrin, F R I C, The London Hospital, Mr H R Moore, and Hospitals for Diseases of the Chest, London, Sir Reginald Wilson

Consultants' Retirement and Ages

Of the 147 consultants who retired during 1958–59 on reaching the age-limit, 29 had an A award, 19 a B award, and 33 a C award Of the 2097 consultants employed (at July, 1959) by boards of governors of teaching hospitals, 1007 were aged fifty or over

First International Symposium of Cybernetic Medicine

This symposium will be held in Naples, from Oct 2 to 4, under the presidency of Prof Aldo Masturzo The general theme of the symposium will be cybernetic methods in modern medicine Further particulars may be had from the secretary, Prof Renato Vinciguerra, Via Roma 348, Naples, Italy

Anglo-French Medical Exchange Bursaries

Further awards will be made in May to young British medical men engaged in clinical or experimental medicine or in biological research

The bursaries, offered by the Institut National d'Hygiène, are tenable at any hospital or research institute in France The value of the grants is 870 N F (about £63) a month, tax free They are normally made for 2-4 months Application forms can be had from the director, Ciba Foundation, 41, Portland Place, London, W 1 The closing date for application is April 21

Conference on Industrial Health

The Industrial Welfare Society and the Advisory Council on Occupational Health will hold a conference at B M A Scottish House, 7, Drumsheugh Gardens, Edinburgh, 3, on Thursday, March 24, at 10 30 A M The subject will be industrial accidents, and the speakers will include Prof J H F Brotherston, Prof J I P James, Mr A B Wallace, and Dr R I McCallum Further particulars may be had from the society, Robert Hyde House, 48, Bryanston Square, London, W 1

Parents' Consent to Operation

At a meeting on March 14 the Sheffield Regional Hospital Board considered a recommendation (*Times*, March 15) to set up juvenile courts in hospitals when consent for an emergency operation on a juvenile is necessary An amendment to refer back the proposal was defeated, and the minute containing the recommendation was automatically approved The National Council for Civil Liberties has protested strongly against the decision and called on the Minister of Health to issue a whitepaper

The Langley prize has been awarded to Dr David Scott, ep-demiologist in the Medical Service of Ghana, for his paper on th epidemiology of human trypanosomiasis in Ashanti

Major-General W A Robinson has succeeded Major General A E Campbell as deputy director-general of Army Medical Services.

Dr D G Evans, medical officer to Philips Electrical Industries, Ltd, has been appointed full-time medical adviser to the Trades Union Congress

A lecture demonstration for general practitioners will be held on Sunday, April 3, at 10 15 A M, at University College Hospital, London, W C 1 Dr T A J Prankerd will speak on the anæmias

The Biochemical Society will hold a meeting on Friday, March 25, at 10 30 A M at the School of Chemistry, University of Leeds

The annual general meeting of the members of the Auxiliary Royal Army Medical Corps Funds will be held at 11 Chandos Street, London, W 1, on Monday, April 4, at 5 P M

The editorial office of the *Biochemical Journal* will move on March 26 from the Lister Institute All communications should be addressed to the secretary to the editorial board of the journal, 133–135, Oxford Street, London, W 1

CORRIGENDA *Renal Changes in Essential Hypertension* —In this annotation last week (p 586) the 5th line of the second paragraph should have ended with the words " cardiovascular derangement "

More Speed, Less Haste —In the fourth line from the end of this leading article last week (p 582) we mentioned Nissen's opinion without including the reference, which is Nissen, R. *German med. Monthly*, 1959, 4, 287

Appointments

BARCLAY, T L, M B Edin, F R C S E part-time consultant in plastic surgery, regional burns unit, Pinderfields General Hospital, Wakefield

FIRTH, GEORGE, M B Leeds, D P H senior assistant county M O and school M O, Ilkley, Otley, and Wharfedale, Yorkshire

GODFREY, L W, M B Lond, F R C S consultant in traumatic and orthopædic surgery, Aylesbury area hospitals

OYLER, C R, M R C S assistant M O H and school M O, Sheffield

POWELL, H D W, M B Edin, F R C S part-time consultant in traumatic and orthopædic surgery, High Wycombe and Amersham group hospitals accident and orthopædic service

QUIGLEY, BRIDGET M A, M B N U I, D P M assistant psychiatrist (S H M O), St George s Hospital, Morpeth, Northumberland

TEMPLEMAN, G H, M B E, M D Leeds, M R C P consultant in chest diseases and medical superintendent, Killingbeck Hospital and Gatesforth Hospital, near Selby, Yorkshire

WEINBERGER, MAURO, M D Genoa, D M R E physician in-charge, Ilford chest clinic

ZOOB, MAX, M D Lond, M R C P part-time consultant cardiologist, Preston Hall Hospital, Aylesford, Kent

The Hospital for Sick Children, Great Ormond Street, London

CALLAGHAN, R P, M B Lond house-surgeon

DANKS, D M, M D Melb, M R A C P house-physician

ELDERKIN, F M, M B Durh, M R C.P E, D C H medical registrar

HSIA, Y E, B M Oxon, M R C P house-physician

KINSBOURNE, MARCEL, B M Oxon, M R C P medical registrar

University College Hospital, London

FLYNN, F V, M D Lond consultant in chemical pathology

PHILPS, F R, M B E, M D Lond consultant in exfoliative cytology

STOKES, JOAN, M B Lond, F R C P consultant clinical bacteriologist

Colonial Appointments

BHEENICK, JEEAN, M B Edin, D T M & H, D A specialist (anæsthetics), Mauritius

CURRIE, J R, M R C S, D T M & H pathologist, Kenya

EVANS, W J M, M B Lond, D P H chief M O, Tanganyika

JACKSON, N J, M B Durh senior M O, St Helena

JAMES, P A, M B Brist, F R C S thoracic surgeon (specialist), Uganda

KERR, W G, M B Edin, F R C S E senior specialist, Tanganyika.

SHARPE, R A, M B Brist M O, Bahamas

SHINE, I B, M B Cantab M O, St Helena

TITMAS, J M, M B Lond M O, Hong Kong

WILKEY, A O, F R C S specialist (surgeon), Federation of Nigeria

Births, Marriages, and Deaths

BIRTHS

PALFREY —On Sunday, Feb 28, to Ann (née Hewetson) and John Palfrey, a son, David Keith—a brother for Michael, Susan, and Christopher

WILKINSON —On March 11, to Clodagh, wife of Dr J B Wilkinson of 3, Greestone Place, Lincoln, a son

The Lancet · Saturday 26 March 1960

COMMUNICATION WITH THE PATIENT

AINSLIE MEARES
M D , B.Agr Sc. Melb , D.P.M
OF MELBOURNE, AUSTRALIA

THE patient comes to us He tells us his symptoms We in our turn make further inquiries as to the development and duration of his complaints, and we inquire about emotional factors in his life. Students are taught that this is history-taking, and it is emphasised that the patient should be given time to tell his story, and that we should be sure to obtain a full account of his past illnesses, as well as the family medical history

However, it is only in the very simplest cases that a medical consultation can follow this plan When there is a psychosomatic component in the illness, the patient almost always skirmishes He mentions a few inconsequential symptoms while he sums us up, in order to see if we can be trusted with the real complaint We soon learn that his past illnesses and his family medical history seem irrelevant to the patient, and any early inquiry into these matters only puts him against us We learn that while he is talking of one matter, the patient unintentionally informs us of other matters The whole business of communication with the patient is something much more complex than our traditional concept of history-taking In fact, we could liken it to a multi-channel system of communication between patient and physician, when each separate channel is communicating different information at the same time.

The Means of Communication

Literal Verbal Communication

The patient tells us about his complaint and about himself by the logical use of words This is obvious However, it is the very obvious nature of logical verbal communication which is likely to mislead us in history-taking It is likely to divert our attention so much that important information which is communicated to us by other channels goes unheeded For instance, it is advised that an effort should be made to correlate the development and exacerbation of symptoms with events in the patient's life story These facts are communicated by the logical use of words The danger is that, in our eagerness to obtain this important information, our attention will be diverted from other equally important communications which are being given to us at the same time

Extraverbal Communication

I have come to use this expression to cover the communication of ideas which are conveyed by the implied meaning of words, as distinct from the logical content of the words This is the meaning which we gather from reading between the lines, as it were There is no logical statement of the idea. It includes innuendoes, and those ideas which are communicated by the simple fact of their omission Extraverbal communication is commonly made by the stress which is given to certain words, or by the tone in which they are spoken On most occasions, the spoken words thus come to communicate two quite different ideas—the logical and the inferred meaning Extraverbal communication is biologically a recently acquired ability It is lost in conditions involving regression. This accounts for some of the difficulty of communication with the schizophrenic. Because we are so accustomed to it, we unthinkingly use extraverbal means of expression, and the patient cannot comprehend our meaning

Unverbalised Phonation

This is the language of grunts and groans, of " Ums " and " Ahs " We must never let ourselves drift into the way of thinking that these are just the noises that a patient under stress of pain or emotion is likely to make Unverbalised phonation has meaning The ideas conveyed are never as clear and precise as those communicated by the logical use of words, but if one closely observes abreacting patients it is seen that quite subtle shades of meaning are often communicated by these grunts and groans Unverbalised phonation is more primitive than verbal communication, and comes to be used most by patients who have undergone some degree of psychological regression, either as an acute reaction to stress of emotion or pain, or as a more chronic reaction Unverbalised phonation is used to communicate primitive ideas of biological importance—love and hate, pain and fear, joy and sorrow If then the physician is in doubt as to the exact meaning which is being communicated, it usually becomes clear if the patient's prevailing affect is taken into account.

Expression

For the most part, the patient's affect is communicated unconsciously by his expression. Anyone can tell from the patient's expression when he is very frightened, or in great pain, or is terribly anxious But expression also communicates very much more complex ideas The patient may consciously use his expression to communicate with us For instance, he may assume a calm expression or an appealing expression An important factor is that our expression is under only very incomplete voluntary control This means that it is used by the patient to consciously communicate ideas, but it also unconsciously communicates ideas, unbeknown to the patient, and, very important, it sometimes communicates ideas of which the patient is aware, but which he tries not to communicate. It is important to learn to recognise to which category the patient's expression belongs Very often one is superimposed upon the other Thus the patient may have a basic involuntary expression of fear, and on top of this he may consciously impose a " please don't hurt me " expression Very often we can see that the patient is consciously assuming a composed expression, but at the same time we see in it the unmistakable signs of anxiety A young man may tell us about his father with apparent nonchalance, while the tensing of his lips and a slight change of colour communicate the conflict which his words deny

Posture and Gesture

In the same way, some elements of the patient's posture and gesture are consciously produced in order to convey meaning to the physician The man who sits down, crosses his legs, and lights a cigarette is telling the physician how relaxed and composed he is It is important to appreciate such communications, as usually it is only an insecure person who has need to express himself in this way My own observations indicate that many business executives consciously cultivate a relaxed posture and expression to cover up a good deal of anxiety The position of the wrist and fingers is often a valuable sign If the patient's hand projects beyond the arm of the chair, the wrist falls into a fully flexed position if the patient is really relaxed, if there is much anxiety, the wrist remains extended

Behaviour

A person performs some act to carry out some purpose in reality We are inclined to think of behaviour as a sequence of such purposeful acts But we must not forget that any act carried out in the presence of others is very often used as a means of expression, as well as fulfilling its purpose in reality The way in which the act is carried out is used as a means of communicating some idea As a very simple example, a child is told to do some task which he does not want to do The child does the task, but does it in such a way as to make it clear that it is done under protest Behaviour expresses the idea as clearly as words The Army uses the delightful phrase " dumb insolence " to cover this type of communication In a similar way, the patient uses his behaviour to communicate Much valuable information can be obtained in this way

The main difficulty of communicating by behaviour in medical consultation is that an interview does not allow the patient much freedom of behaviour We learn more from a patient's behaviour when we come to the physical examination The patient may have given little indication of his inhibited nature until he is asked to take off his clothes In this respect, we must not forget that many inhibited persons overcompensate, so that a patient whose behaviour leads him to a rather blatant exposure of his nakedness may in fact be extremely inhibited We must read the communication correctly It surely means, " I shall show him I am not shy and sensitive about these things "

There are some facets of our behaviour which are particularly important as non-verbal communication The way in which we greet the patient is significant We must be careful not to greet inhibited patients too warmly, for they are afraid of close emotional contacts, and if they are approached too closely, they withdraw into themselves Touch is a particularly significant means of non-verbal communication To take the patient's hand when he is struggling with emotion gives him the feeling that somehow his problem is shared with the physician Any attempt to communicate the same idea by the logical use of words is hopelessly awkward, and embarrasses the patient On the other hand, any inept use of this mechanism, which might bring us to touch the patient in inappropriate circumstances, only informs the patient that we are insensitive to his state of mind

In another way, it can often be seen that the various elements of the patient's behaviour fit into a pattern, so that he is seen to be playing a role This in itself is a communication to the physician The patient may assume a role of importance The meaning may be " You can see I am an important person, you must treat me as such" The physician in his turn thinks " What makes him so insecure? " It may be that the patient's behaviour communicates the idea, " I need your help very badly, please do not let me down " In such a case, the physician moves closer to the patient emotionally, so as to support him

Sometimes the patient behaves in such a way that he is really communicating with the physician by means of symbolic acts There are grades of such symbolism It may be the conscious symbolism of everyday convention, or it may be deeply unconscious The offer of a cigarette is a conventional symbolic act communicating an offer of friendship The behaviour of a regressed schizophrenic may be a communication in terms of Freudian symbolism

When we are considering the patient's behaviour as a means of communication, we must remember that the situation may be complicated by transference phenomena A hostile reaction to an authoritative physician may be a release of emotion felt for an authoritative father, but transferred to the physician

Primitive or Sophisticated?

The different channels of communication really belong to different periods of biological development Thus non-verbal communication in general is more primitive than logical verbal expression, and extraverbal communication is more recent, more advanced, than logical verbal expression However, there are some non-verbal communications which are quite sophisticated This type of communication is seen to good advantage in a well-acted modern comedy There is no basic simplicity about these communications They are witty, cute, and subtle This type of non-verbal communication is culturally determined, and is quite distinct from the primitive type. Sometimes the patient will use this type of communication in his initial testing out of the physician An important point is that the prepsychotic schizophrenic loses his ability to follow this type of communication This is one of the factors which go to account for his general bewilderment On the other hand, even when the illness is well advanced, he retains the ability to use the primitive type of non-verbal communication, and this becomes an important means by which the physician maintains contact with him

Silence

As regards behaviour, there is another point Silence and the lack of activity does not necessarily mean an absence of communication Silence is readily used to express hostility, but it can also express sympathy and understanding In itself it is an aspect of behaviour, and in certain circumstances may be charged with meaning which the sensitive physician is able to interpret

Content of the Communication

The Conscious Communication of Fact

This consists of all the ideas which are communicated by the logical use of words It includes the patient's description of his symptoms, the details of his life story, and the logical correlation of this information This is what some teachers regard as a psychosomatic history Such a view is obviously too circumscribed, since it ignores pertinent information which is available by other channels of communication

The Unconscious Communication of Conflict

The successful treatment of any illness which is emotionally determined centres around the recognition and resolution of psychological conflict. Basically, we recognise psychological conflict when we observe disturbed emotion in the patient at a time when we know that he has some particular thought in his mind *In* actual practice, this information usually does not come to us as a single communication Different elements are communicated through different channels. Thus a common situation is that we learn what ideas are in the patient's mind from what he is saying, but the emotion concerning these ideas is usually communicated non-verbally. The patient talks of his father, and at the same time his anger is communicated extraverbally by his manner of speech and non-verbally by his expression. The introvert youth talks of his mother, and by the slowing of his speech makes an extraverbal communication of the emotion which he feels for her. The girl talks of her boy, and tells us he was only a friend, but her expression communicates her emotion. The business man talks of his work, of his office, and then of his secretary and there is a change in his expression. In other cases, the actual thought content itself is communicated non-verbally. With the patient who is composed during the interview, but who shows anxiety at the prospect of physical examination, his behaviour and his posture show that his thought concerns his body, probably the sexual part of his body, at the same time his emotion is communicated by his expression, his gesture, and other elements of his behaviour.

Communication of Affect

We may discover the way the patient feels, his mood, by all or any of the channels of communication. In this respect, logical verbal communication is often particularly unreliable. Many hysteroïd persons say that they feel terribly depressed, when in fact they are not suffering from psychological depression. The patient is not consciously lying. It would seem rather that the statement should be accepted, not at a logical verbal level, but rather as an extraverbal communication meaning that his difficulties are so great that they should cause anyone to be depressed. More important are those mildly depressed patients who insist that they do not suffer any depression. Some people of rather sterling character feel that depression is weakness of mind, and sometimes they will deny to the physician and to themselves any feeling of depression. However, their affect is clearly communicated by their expression, their posture, and their behaviour.

Communication of Attitudes

During life we develop certain definable attitudes towards various matters. During the interview, if he is given a chance, the patient will communicate these attitudes to us. It is important that we recognise them, for they often lead us to the area of significant psychological conflict. Furthermore, we have to give consideration to the patient's attitudes in our medical management of the case. His attitudes towards religion, sex, family life, and morality will influence us in the way in which we approach these matters with him. These attitudes are usually communicated by the patient talking of some subject, and at the same time unconsciously disclosing his emotion by non-verbal means.

Communication of Habitual Patterns of Psychological Defence

We must remember that in the initial part of the interview, the patient is almost always on the defensive. There is something personal about consulting the doctor. He is a little ill at ease. It may be that deep down he associates his complaint with guilt about things he has done. During this phase of the interview, the patient unconsciously communicates to us the nature of the psychological defences which he habitually uses in his everyday life. He may keep holding himself in check, he may want to withdraw, he may assume a superiority, he may be ingratiating and over anxious to please, he may show an ill-disguised aggression.

Appeals and Threats to the Physician

Communications of this nature are surprisingly common, but they are seldom made by the logical use of words. The visit to the doctor is often more disturbing to the patient then he himself realises. He is driven to make frantic appeals. His pride and social convention prevent their logical expression in words. The ideas are so humiliating that he is not fully aware of the content of the communications. "I am so weak, you are so strong, help me." "You see, I have had such an unhappy childhood, it is not all my fault." "If you don't help me, I will kill myself."

Communication in Different Conditions

In our everyday life, we notice that some people show a tendency to use one channel of communication in preference to others. These tendencies seem to be determined by racial and cultural influences, as well as by individual personality structure. Thus a Parisienne actress quite naturally uses the non-verbal communication of expression and gesture in a way which would be considered pathological in a Scot. Persons in any culture who are inhibited, rigid, and precise tend to emphasise the logical use of words. Some intelligent people of subtlety favour the extraverbal channel, and communicate many of their thoughts by the meaning between the words, rather than by the meaning of the words themselves. The person with a free-flowing emotional life is continually communicating, by expression and behaviour, all those shades of feeling which simply cannot be adequately expressed by the logical use of words. In dealing with our patients, these are all matters which must be taken into consideration.

However, in certain types of psychiatric conditions, there are quite gross changes from one type of communication to another. Thus the early schizophrenic soon loses his capacity for extraverbal communication and sophisticated communication by means of his behaviour. As his illness progresses, his logical use of words is impaired. He falls back on other means of communication. He uses words to communicate by virtue of their symbolic significance, and not the logical meaning of the words themselves. When there is regression in schizophrenia, the patient relies more and more on non-verbal communication. This is just what we should expect. He is returning to childish and infantile patterns of behaviour, so we might anticipate that he will communicate with us in the same way as would a child or infant. We must not dismiss the matter by recording that the patient is behaving in a peculiar way, we must recognise that he is using a different channel of communication, and we must tune in, as it were, so that we can read his message clearly. The way in which we tune ourselves in to such communications is the whole art of psychotherapy with psychotic patients.

With the case of mild involutional melancholia, the expression and posture will often communicate an unmistakable feeling of depression which the patient may deny in words.

Other patients also show a very definite choice of certain channels of communication. For instance, the obsessive is essentially meticulous, rigid, and precise. He likes to use words logically. Nevertheless, his communications by this means often do not convey his meaning very clearly. He is characteristically given to doubting. As a result of this, he finds that he has to repeat to us so many inconsequential details that the main burden of his communication is lost in the process This, of course, is one of the difficulties of psychotherapy with obsessives But in addition to his liking for logical verbal communication, the obsessive shows a strong tendency to make unconscious symbolic communications by means of his obsessive rituals and compulsive acts

As opposed to the obsessive, the hysteric favours non-verbal means of communication When we are interviewing such a patient, we must always expect the really important ideas to be communicated by expression and behaviour, so we must guard against being misled into paying too much attention to the logical content of what the patient is saying

It is well to note that the anxious patient often employs the logical use of words to maintain a conscious stream of communications about symptoms and superficial conflicts These communications are in reality a defence The patient is unconsciously driven to keep talking in order to prevent the physician from inquiring into matters which are painful to the patient

The Physician Communicates with the Patient

The patient may discuss his symptoms quite readily, but when it comes to matters of his emotional life, he is often inhibited and reluctant to talk We have to keep the interview going, and bring him to disclose his psychological conflicts This is the art of interviewing We keep the patient talking by appropriate unverbalised phonation in the form of interrogatory grunts By this means we inform him that he has our undivided attention, and that we are waiting for him to quietly tell us the worry on his mind We must convey ideas to him that he can trust us, that we understand, that we are not hostile to him for his shortcomings The ideas are communicated non-verbally, by our manner and behaviour The way in which we lapse into silence, and the way in which we touch the patient, are particularly significant in making communications of this nature

Our therapeutic communications with the patient include the establishment of rapport This is the doctor-patient relationship which allows of effective psychotherapy, and which we can purposefully manipulate to the patient's advantage during the different phases of our interviewing This is an emotional relationship and is established by the extraverbal and non-verbal communication of emotion, by the way in which we talk with the patient and our behaviour towards him

In our actual treatment, we may find that we can help the patient with suggestion in one form or another An essential factor in suggestion is that it is the process which determines the uncritical acceptance of ideas Hence, if we would use suggestion, we must convey the idea to the patient in a way which does not arouse his critical faculties, which would put a stop to the operation of the process of suggestion So ideas which we want to convey to the patient for this purpose should be communicated by non-verbal means as far as possible

We may wish to give the patient insight into some particular matter We must always let it come to the patient Even if it is quite simple, a logical verbal communication of insight is usually rejected by the patient, and only produces anxiety and hostility We must talk around the subject We communicate extraverbally and non-verbally until the cold logic of the situation comes to the patient

At the conclusion of the first interview, the physician must make some kind of a statement to the patient about his condition, and how the physician proposes to help him This is a logical verbal communication However, the physician must do something more than this He must reassure the patient This is an important part of doctoring It does not mean that we tell the patient that he will soon be better, when in fact we know that he will not It means that we communicate the idea to the patient that we understand him in his trouble, and that we will help him and stick by him through to the end Such an idea cannot be adequately conveyed by the cold and logical use of words The patient leaves us without ever mentioning these things, but he knows them to be true from our behaviour, and the general way in which we have conducted ourselves with him

Some Practical Considerations

Barriers to Communication

These operate at different levels of psychological integration, according to the nature of the ideas concerned The most superficial barrier is simply the feeling of shame or hurt which prevents the patient from expressing some matter which he finds humiliating The physician removes this barrier by establishing rapport with the patient, so that he feels he can trust the physician with his personal secrets

The next barrier arises when the significant idea is suppressed The patient has put the idea out of his mind, and simply will not tolerate the thought of it This barrier is removed in states of emotion, and in conditions when the patient is off guard The physician may need to provoke the patient to abreaction before he will communicate this material

The last barrier is represssion The significant material may be completely beyond the patient's consciousness Special techniques, such as free association, hypnosis, or narcoanalysis, may interfere with the repressive mechanism, and allow the communication of these ideas However, a great deal of repressed material may be communicated unconsciously by the patient by non-verbal means Thus the latent homosexual may be quite unaware of the nature of his condition The conflict is completely repressed, yet it is communicated to the physician by the patient's behaviour

The Physician Makes Inadvertent Communication

We have seen that the patient is unaware of many of the communications which he makes to us In a similar way, there is real danger that the physician himself may unconsciously make inadvertent communications to the patient The physician may unconsciously disclose to the patient his own weakness, in a way which causes the patient to lose faith in him This, of course, is distinct from those occasions when it is wise for the physician to disclose some weakness in order to increase the patient's feeling of trust There may be something about the patient which the physician does not like There is always the danger that this might be communicated to the patient by expression or behaviour A common hazard is the unconscious communication of moral criticism of a patient who discloses his antisocial behaviour

The Manipulation of Anxiety

If the patient is too anxious, he becomes inhibited, and is unable to communicate freely with the physician On the other hand, if the patient is free from anxiety, he feels comfortable and secure, and he lacks the motivation to communicate ideas which are hurtful to him So the success of a difficult interview depends very largely on the physician's ability to regulate the amount of anxiety which the patient is experiencing Anxiety is reduced by moving to a closer affective relationship with the patient, by reassurances, by sedation, by relaxation, and by suggestion Anxiety is increased by emotional withdrawal from the patient, by physical examination, by placing the patient in unfamiliar circumstances, and by inquiry about events in his life which are known to have occasioned conflict

Manipulation of Affective Relationship

The ease with which the patient communicates depends very largely on his affective relationship with the physician This relationship is capable of quantitative variations in intensity, and also qualitative variations in nature Thus there must be a professional relationship, so that the patient trusts the physician, but if it turns into a social relationship, it becomes a barrier to the communication of intimate matters

Learning the Language

It is clear that the physician who would be sensitive to what is going on in the patient's mind must learn the language of each of the various channels of communication. But he must do more than this He must learn to use non-verbal communication himself This is necessary because some ideas can be effectively communicated only by this means It is the only effective channel of communication for the patient who is under emotional stress, and the patient who has regressed And in any field of medical practice, the physician is continually dealing with patients in these circumstances

Summary

There is a multi-channel system of communication between patient and physician. These different channels are formed by literal verbal, extraverbal, and non-verbal modes of communication. The physician receives different messages through different channels at the same time. His attention to verbal communication should not lead him to disregard information available through the other channels Some ideas can be effectively communicated only by non-verbal means To understand his patients, the physician should be competent in the language of non-verbal communication

EXTERNAL SPLINTAGE AS A CAUSE OF MOVEMENT IN FRACTURES

J H HICKS
M.B Birm, M Ch Orth Lpool, F R.C S
SURGEON, BIRMINGHAM ACCIDENT HOSPITAL

THE failure of external splintage to prevent displacement (as shown in figs 1 and 2) is not uncommon. In a series of 50 forearm fractures Evans (1951) recorded some loss of position in 9 On occasion there can occur a ten-degree angulation or a complete diameter shift in the shaft of a long bone, a considerable pronation or supination twist in a forearm, or a twenty-degree tilt in the lower fragment of a Colles fracture There was nothing out of the ordinary about the cases illustrated in figs 1 and 2, and the splintage was orthodox. It therefore seems probable that small movements can occur inside conventional splints, at least in the early stages of treatment, and that when they stop it is not by any virtue of the splint. This suggestion is supported by the occasional case in which the patient complains that he can feel the bone ends moving against each other inside the plaster case, even though the application of his plaster case has followed the usual tenets

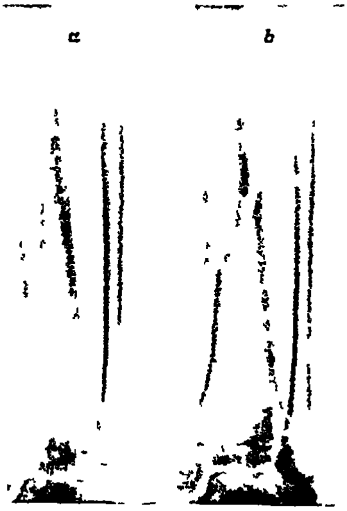

Fig 1—Undisplaced spiral fracture of tibia (*a*), and same fracture two weeks later

One purpose of this paper is to add weight to the suggestion that small movements in fractures treated conservatively are common Attention will be concentrated not on deformity of large amplitude—perhaps the result of a single movement, whose undesirable result is merely the abnormal shape of the united bone—but on movement of small amplitude, continually repeated, and not necessarily giving rise to significant final deformity Elsewhere I have shown that prevention of these movements has an important influence on union and on the final function of the limb (Hicks 1959)

The experimental work was started with the intention of confirming two clinical impressions

1 That in the conservative treatment of fractures this movement of the one fragment relative to the other is not due to imperfect technique but to an unsound principle.

2 That continual movement at the fracture site may be present in the early stages, not only in those cases where a permanent deformity becomes established but in the majority of conservatively treated fractures and perhaps in all

A third point, which will ultimately prove to be of greater importance, emerged theoretically and was confirmed experimentally. This was

3 That external splintage can positively *cause* movement (not simply *permit* movement) at a fracture site

Precise knowledge of what treatment does and does not do is essential in order to correlate it with any observations on fracture behaviour The fact that movement is usually

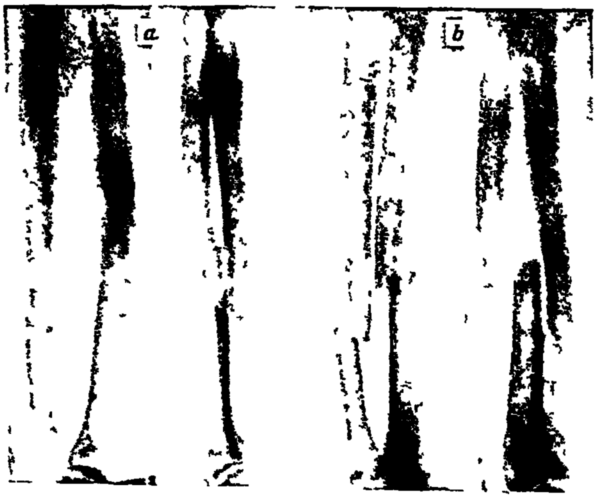

Fig 2—Fractured radius and ulna after reduction (*a*) and one week later (*b*).

found to have ceased at the end of the period of splintage is no proof that the splintage brought about the cessation Everyone is familiar with the unsplinted fractures that become spontaneously fixed—that is, united The natural splintage of callus must have been responsible for this, and it may well be that natural splintage is equally responsible for the cessation of the last few degrees of movement in splinted fractures also No-one knows in how large a proportion of splinted fractures this occurs—that is, how often artificial splintage plays no part in fixing the fracture except against gross movement

Passive Resistance of Movement

To investigate the ineffectiveness of a plaster in fixing a fractured tibia, the following experiment was done on freshly amputated legs

A specimen with a comminuted fracture was taken and was enclosed in a long plaster case The amputation was through the lower third of thigh, but an orthodox case was imitated as faithfully as possible by completely enclosing the proximal end except for the bone The plaster was applied more tightly than would ever have been risked in clinical practice, and was moulded with all possible care to give the firmest grip, and it held the knee in the requisite few degrees of flexion A small window was cut over the fracture site, and through this the behaviour of the fracture ends could be observed Using only such forces as could be applied by the fingers it was found that one fragment could be made to shift 2 5 cm relative to the other Rotation to the extent of twenty degrees and angulation to the extent of six degrees were just as easily obtained The forces required to produce the first three or four degrees of angulation or half-centimetre of shift were infinitesimal compared with the forces likely to obtain in clinical practice Only when considerably larger movements were attempted was any appreciable resistance offered by the splintage

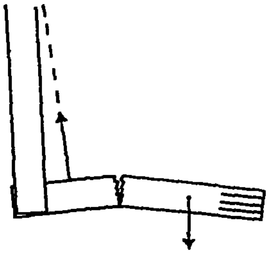

Fig 3

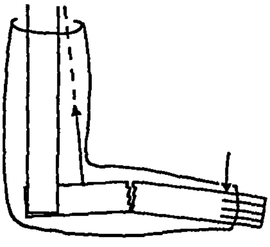

Fig 5

Fig 3—Angulating stress produced by a combination of weight and muscle pull

Fig 5—Angulating stress, similar to that shown in fig 4, produced when flexion is attempted against the resistance of external splintage

Until more than 5° of angulation occurs, the direct splintage effect of the plaster provides almost no protection against angulation

In a second specimen shift was even greater (over 3 cm) and compression-distraction was as much as 0 4 cm Furthermore in this specimen *movements of considerable magnitude* were also produced by taking hold of the femur and using it to move the whole limb with its enclosing plaster, as would occur in real life if a patient were alternately standing up with the limb pendant and sitting down with the heel resting on the floor

That movement can occur however tightly a plaster is applied is not surprising since there is always at least half an inch of soft padding material (the subcutaneous tissue, whose function it is to facilitate sliding of skin over deep structures), and in addition often an inch or two of muscle, between splint and bone Nevertheless some leading authorities act on the assumption that a "properly" applied plaster case can provide "absolute fixation" The large amplitude of movements seen, even after making ample allowance for experimental imperfections, and the small forces required to produce them, were very revealing

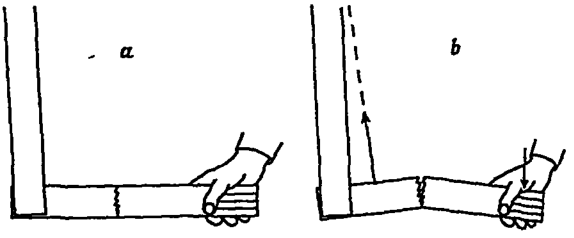

Fig 4—Angulating stress produced when movement is attempted against resistance (*a*) no tension in muscle, no resistance, and no resulting angulating stress, (*b*) tension in elbow flexor, resistance to flexion, and resulting angulating stress

Occasionally devices such as the three-point plaster described by Charnley (1950) may ensure improved fixation by taking advantage of such inherent stability as may exist in the shape of the fracture But only when the fracture is transverse or will interlock in a stable manner and when the soft tissue hinge is intact are the conditions suitable for applying the three-point principle Such cases are in a minority, and the method will not work when the fracture is spiral or comminuted or when the soft tissue hinge is torn

Production of Movement by Splints

The above movements were produced by more or less artificial forces There are, however, natural forces arising from the patient's own muscle action There is reason to believe that these may be redirected by external splintage inwards on to the fracture site and thus cause movement

The forearm will be used as an example Fig 3 shows diagrammatically a forearm held out horizontally, its weight (tending to produce extension) balanced by the pull of the muscles (tending to produce flexion) These two forces create an angulating stress in the bones which would, if they were fractured, result in *forward* bowing In fig 4 the hand is represented as being held still by the experimenter While the subject is not contracting his muscles the fracture remains free from angulating stress, but when the subject attempts to flex his elbow, and if the experimenter resists the attempted movement (as in fig 4*b*), angulation again will be produced at the fracture site In fig 5 the limb is represented as enclosed in a long plaster case which has a comparatively firm hold on the hand and therefore fixes it to the upper arm as though to a baseboard In this example the plaster is the agent that provides the resistance to movement so that when muscles act on the proximal fragment angulating stress is produced at the fracture as in the previous instances Thus it appears that suitable conditions for causing movement at a fracture site are established by the very splintage that is intended to prevent it

It is not only the flexor muscles that can be the direct cause of movement In the conditions shown in figs 4 and 5, resistance is offered to movement of the hand in *any* direction, and a posterior bowing *deformity* is just as readily produced (by the triceps) as an anterior bowing by the flexors Alternatively a rotation movement could be caused by the rotators In brief, wherever a muscle acts on the proximal end of a bone and resistance is offered to movement of the distal end, or vice versa, movement may be caused at a fracture site

Rotation is likelier than angulation because of the particular inefficacy of a cylindrical plaster case in controlling rotation The operative forces can be demonstrated fairly convincingly by anyone on himself

If, with the arm free and elbow partly flexed, pronation and supination are attempted, the hand will pronate and supinate readily No stress occurs in the forearm bones other than the small forces required to support the weight of the hand and to overcome inertia and air-resistance If, however, someone else takes the hand as in a handclasp and holds it firmly while pronation and supination are attempted, stresses now occur, and can be perceived, in the radius and ulna if there were a fracture this might easily be displaced Anyone who has a long plaster case applied to his own arm can feel the firm hold it has on his hand, preventing it from rotating, and he can feel the strain in his own bones when he attempts to pronate or supinate against the unyielding resistance In each case the strains cease as soon as either he ceases contracting his muscles or the resistance ceases—that is, when the handclasp is relaxed or the plaster case is removed The stresses that then remain are once again only those due to gravity

In the lower limb, from a knowledge of the direction of the talo-calcaneonavicular axis (Hicks 1953) it can be deduced that attempts to invert and evert the foot against resistance will tend to cause the lower fragment of a fractured tibia to rotate externally and internally respectively upon the upper fragment To prove this experimentally the actions of peroneus brevis and tibialis posterior were simulated in another amputation specimen which had been enclosed in a case

Three windows were cut in the plaster—one over the fracture site and one each over the tendons concerned. Two Kirschner wires were driven by their points into the bone—one just above the fracture and one below—and arranged to lie parallel with each other and fairly close together so that small degrees of movement of one fragment relative to the other would be rendered obvious Loops of the two tendons were hooked out over an arrangement of pulleys that ensured equal pulls distally upon the origin and proximally upon the insertion, in imitation of normal muscle action When tension was applied to one or other of the tendons the lower fragment of the tibia was observed to rotate as expected and in the direction predicted by theory By alternately pulling on the two tendons as much as 12° of rotation was obtained at the fracture site In this movement the distal fragment is the active and the proximal the passive participant. The power comes from the invertor/evertor muscles acting on the foot, and the drive is transmitted thence proximally through the talo-calcaneonavicular joint in much the same way as torque is conveyed along the transmission system of a car through the universal couplings The relative movement between the two fragments would have been even greater than 12° but for the fact that the passive upper fragment followed the movements of the lower one to some extent. Thus, if the plaster case had really done what it is popularly believed to do—that is, taken a firm hold upon the proximal fragment—the amount of movement of the lower fragment relative to the upper would have been even greater When the foot portion of the case was removed—that is, when the resistance to foot movement ceased—the effect disappeared.

Thus the forces generated by the muscles, instead of being exteriorised as movements of the limb, are so to speak turned inwards and act with equal but opposite effect upon the fracture site The more effective the plaster at resisting pronation-supination in the hand or inversion-eversion in the foot, the more effectively are the muscle forces inturned This feature is not, of course, confined to the forearm and leg, although these happen to be particularly susceptible sites Wherever in the body external splintage provides resistance to the free movement of a joint, muscles can cause movement at an adjacent fracture This is an example of a more general rule when a muscle acts, if it cannot cause movement of the joint it will tend to cause movement at the fracture site If the plaster cases in the above examples had not extended beyond the wrist or the ankle or above the elbow or knee, the muscles would not have tended to cause movement Thus, contrary to popular belief, long plaster cases that interfere with movements of the joint above or the joint below provide the opportunity for muscles to cause movement at the fracture site, and the patient only has to exercise these muscles for the movement to occur As regards the magnitude of the forces, without splintage the deforming force can be no larger than is consistent with the weight of the limb (fig 3), whereas with splintage the forces may be of any magnitude, being limited only by the strength of the participants and of the plaster case (figs 4 and 5) it is not beyond the bounds of possibility that the movements so caused may affect the process of union

Some doubt may remain as to whether the conditions obtaining in the above experiments ever arise in real life, especially as contracting muscle bellies are popularly supposed (though never proved) to have some supportive action on a fracture Another experiment was therefore carried out, this time upon a patient who had delayed union of a fractured ulna, certain characteristics of which aroused the suspicion that it was due to persistent movement at the fracture site

This fracture had been treated orthodoxly by a plaster case extending from the necks of the metacarpals to the upper third of the arm so that, according to popular teaching, proper fixation had been provided, whereas, according to this new theory, suitable conditions for the creation of movement had been present An operation being necessary, with the patient under an anæsthetic electrodes were bandaged over the forearm muscles and a well-moulded long plaster case was reapplied Through a window Kirschner wires were driven into the ulna, one above and one below the fracture site, to act as pointers Faradic current was then switched on and off to make the muscles contract. The pointers revealed, each time this was done, that movement occurred at the fracture site One result of this experiment was a decision to carry out real " fixation ", whereupon the fracture united without any graft being necessary (This is to be described more fully in a subsequent paper)

Surgeon and physiotherapist, with their modern enthusiasm for early " exercises ", encourage the very muscle contractions that can cause movement of a fracture in plaster The patient referred to above had not been told to avoid exercise in the early weeks of treatment, and he remembered noticing pain in the region of the fracture when he had tried to twist his arm inside the plaster

The amplitude of movement in this instance was seen to be about 2–3°, and this probably represents the usual order of magnitude of these movements This suggests that they may be common, but undetected because of our inexact methods of clinical and radiological examination. Each time a limb is X-rayed it is placed in approximately the same position so that the fragments are likely always to settle into the same position, even though they may have been moving relative to each other in the intervening periods The fact that we do not ordinarily see movement therefore is certainly no proof that it does not occur

High-power Low-amplitude Movement

Two or three degrees of movement might seem to be unimportant, easily stopped, and unlikely to have any harmful effect on a fracture Not only the amplitude, however, but the power with which a movement takes place must be considered Movement can be of low power or of high power, and it is a mistake to think of high-power movement as necessarily of large amplitude For example, a train going over a bridge bends the bridge The bend is only a fraction of a degree, but the power behind the movement is, in terms of human endeavour, irresistible Similarly the movement at the fracture site, although small, can be of high power It is the fact that, in the circumstances described, this movement is " power-driven ", brought about by muscles used to contracting with forces of fifty or a hundred pounds, that gives some cause for concern This should be kept in mind as a possible explanation for the misbehaviour of certain fractures in practice

Discussion

No question is being raised as to the positive action of external splintage against forces from outside—for example, gravity or accidental blows Against these, the larger and better fitting the splint, the greater is the fixation It is against forces coming from within that a splint's effect is inverted These latter forces scarcely act at all on the fracture in the absence of external splintage, but they do so in increasing degree as joints proximally or distally are included

It is not intended to imply that all fractures treated in long plasters are inevitably and continuously subjected to movement Firstly, almost all plasters at some time become loose or soft, or break, or they are applied for only a short distance beyond the adjacent joint When the external splintage fails to limit the movement of the joint above or the joint below, movement at the fracture site due to muscle action does *not* occur Thus, paradoxically, plasters that are too short, too loose, or otherwise badly applied (by present criteria) may result in less imposed movement at the fracture site than those that are " correct " In addition, if the patient does not contract his muscles there will be no forces to be inturned Thus by avoiding exercises both voluntarily and reflexly, and by obeying the dictates of pain to let the limb lie completely still, the patient himself may succeed in avoiding movement at the fracture site It is probably in these indirect ways that present treatment succeeds—when it does succeed—rather than by any direct splintage effect

The imposed movement described here is always of low amplitude, and one might be excused for dismissing it as unimportant were it not that some fractures still unaccountably do badly, particularly as regards non-union and joint stiffness The suggestion that joint stiffness is caused by movement at the fracture site has already been made (Hicks 1959) It now seems possible that the " invisible " movement described in the present paper may be the factor responsible for the stiffness consequent on plaster treatment—in other words, that the stiffness is being caused not so much by the immobilisation of the joint as by the failure of immobilisation of the fracture

Summary

External splintage is effective only in so far as it prevents gross movement at a fracture site It is very ineffective at preventing small movements Whole-diameter shift, 20° of rotation, or 5–10° of angulation, can certainly occur inside a conventional plaster case, and evidence suggests that such movements do occur

External splintage plus muscle contraction tend to *cause* movement at a fracture site Many of the rules of splintage (e g , having the plaster full-length and well-fitting, and extending it beyond the joint above and the joint below) increase the likelihood of this movement Muscle " exercises " are the motive power of the movement

ENVIRONMENTAL STAPHYLOCOCCAL CONTAMINATION

A STUDY BY A NEW METHOD

W D Foster
M D Cantab
LECTURER IN PATHOLOGY,
LOUIS JENNER LABORATORY, ST THOMAS'S HOSPITAL, LONDON, S.E.1

ALTHOUGH some outbreaks of staphylococcal infection of clean operation wounds have been shown to be due to organisms from nasal carriers (Sompolinsky et al 1957, Pennikett et al 1958) or from members of an operating team with superficial sepsis (McDonald and Timbury 1957, Mitchell et al 1959), in many outbreaks no particular source has been identified Autoinfection may be responsible in some cases, the organisms having come from the patient's carrier sites in the nose or perineum, but often the organisms have been transferred from neighbouring infected patients either directly by way of the hands, &c , or indirectly by airborne particles from dressings, bedding, or floor dust

This paper is concerned with possible means of cross-infection from other patients Hitherto, it has been hard to say how much environmental contamination occurs Use of the slit-sampler means that only airborne particles can be sampled, and it is well known that the number of organisms found varies greatly from hour to hour, depending largely on such activities as bedmaking and ward sweeping Settling-plates suffer from the same disadvantages, with the additional risks involved in their having to be exposed for at least half an hour—not only disrupting ward routine but possibly being broken With the impinger methods of floor-dust sampling, such as that described by Williams (1949), it is impossible to estimate how much of the dust is actually sampled, or to obtain figures for an area of given size Gentles (1956) described a direct floor-sampling method, but its use for taking a large number of samples would be laborious

For these reasons I have devised a new method. By applying slabs of agar (reinforced with gauze) to the floor or other surfaces, one can estimate the number and type of organisms on a unit area By use of these " impression plates " it has been possible not only to assess the degree of environmental contamination in wards but also to evolve methods for its reduction

Methods

Media —For isolation of *Staphylococcus aureus* from wounds and skin, blood-agar plates were employed, and for the impression plates usually plain nutrient agar The plates were incubated overnight at 37°C and then left on the bench for a further 24 hours Colonies of *Staph aureus* were recognised by their colonial appearances and confirmed by the slide coagulase test

Surface sampling and counting —The impression plates were prepared by laying a strip of sterile bandage $1\frac{1}{2}$ in wide, right across an empty petri dish and pouring agar over it With such a stiffening, it is possible, with forceps, to remove the disc of medium from the petri dish, press its undersurface

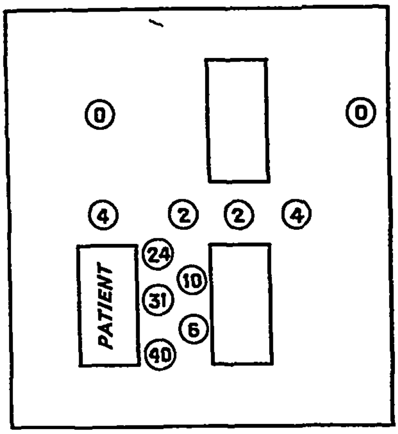

Fig 1—Numbers of *Staph aureus* per impression plate in different positions in a ward containing a case of impetigo

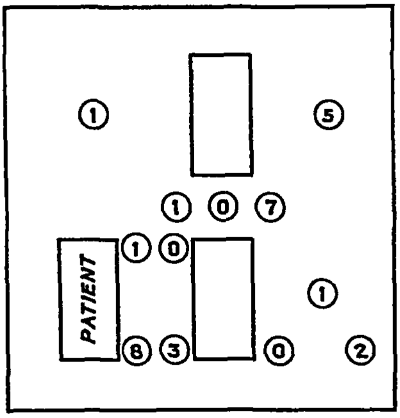

Fig 2—Distribution of *Staph aureus* in the ward 2 days after the discharge of the case of impetigo

evenly on the floor, pick it up, and return it (contaminated surface uppermost) to the *lid* of the petri dish After incubation the number of colonies of staphylococci developing can be counted Although all the organisms from the area sampled are not picked up, counts of the total number of all organisms on different occasions showed that the method gave fairly reproducible results

Results

Contamination of Environment by Individual Patients

To determine how heavily the environment can become contaminated by coagulase-positive staphylococci, a small three-bed ward which had just been fumigated was studied

TABLE I—NUMBER OF STAPHYLOCOCCI PER PLATE AT DIFFERENT DISTANCES FROM BED

—	1 ft	2 ft.	3 ft	5 ft
1	39	37	13	0
2	33	18	14	7

4	11	18	24	4
5	0	21	6	19
6	33	0	6	0
7	25	0	10	16
8	28	34	0	6

A patient with a small patch of impetigo was admitted, and *Staph aureus* (types 71 and 3c) and group-A streptococci were isolated from the lesion. About 24 hours after admission, blood-agar settling-plates which were exposed for 30 minutes at various positions around the bed grew an average of 3 0 colonies of *Staph aureus* and 0 5 colonies of *Streptococcus pyogenes* per plate At the same time impression plates using blood-agar containing the strip of bandage were taken at different positions in the ward Fig 1 shows the distribution of the plates and the numbers of *Staph aureus* picked up by each No streptococci were picked up from the floor, but phage typing confirmed that most of the staphylococci on the floor had in fact come from the patient.

The patient remained in the ward for 4 days and was then discharged because the lesion had healed 2 days later, before another patient was admitted, another set of impression plates was made from the floor These showed that all the organisms of the patient's phage type had either died or been removed by the ward routine cleaning which did not include any antiseptic methods (fig 2)

If, as the above experiment suggests, a patient with comparatively small lesions can heavily contaminate his environment, contamination by a patient with a severe infection may be even greater This was clearly demonstrated in the case of a patient with a staphylococcal lung abscess

Impression plates were taken from the floor, in four zones 1 ft, 2 ft, 3 ft, and 5 ft from the edge of the bed Representative colonies from the patient's sputum and each zone on the floor were all members of phage type 54 (table I)

Use of the Method to Investigate Cross-infection

The impression plate method was used in the study of a small outbreak of wound sepsis in a ward

A male general surgical ward had been cleaned and fumigated. After it was reopened, two patients (one with infection of an amputation wound and the other with a postprostatectomy urinary infection, both caused by *Staph aureus* type 77) were admitted 7 days later a third patient, whose laminectomy wound was known to have been free of *Staph aureus*, had the wound probed in the ward, and 2 days after that the wound was found to be also infected by a type-77 strain The nose of the sister who probed the wound was free of *Staph aureus* In the next 3 months there were four more cases of infection with this type of staphylococcus, as well as several infections with other strains

From time to time an impression plate was taken between each bed, and table II shows the average number of staphylococcal colonies per plate From fig 3, which shows the numbers and distribution of *Staph aureus* on one particular day, it will be seen that the highest counts were obtained in the neighbourhood of infected patients

Use of the Method to Investigate the Effect of Ward-cleaning

Although the floor was probably being continually re-contaminated by *Staph aureus* from the infected wounds, it seemed worth ascertaining whether more stringent ward-cleaning would lessen the contamination

The routine method employed was to wash the linoleum squares of the ward floor with a detergent once a week and swab them daily with 'Sudol' solutions Although the dilution of sudol prescribed by the manufacturers was 1/120, the strength recommended for the ward was 1/80, but in practice this was achieved only approximately Impression plates taken before and after washing the floor with detergent showed a reduction from 56 *Staph aureus* per area to 14, and swabbing with sudol by the wardmaid reduced it from 114 to 59 In view

(a) New cleaning routine, 1/40 Sudol to floors
(b) Reversion to old cleaning routine, water only to floors
(c) Anti-staphylococcus campaign

of the number of staphylococci surviving this treatment, experiments were undertaken in which an area of laboratory floor was contaminated with a broth culture of *Staph aureus* and when dry was wiped with cotton-wool soaked in sudol of different strengths Impression plates taken afterwards showed that not until a strength of 1/40 was used was killing effective

Table II shows the results obtained when 1/40 sudol was used in the ward The number of *Staph aureus* fell considerably

After 10 days the use of sudol was stopped, and impression plates taken 2 days later showed the staphylococci to be as numerous as before It was thus clear that strict attention to ward-cleaning may in itself reduce contamination dramatically

Subsequent History of the Ward Investigation

Fig 4 shows that after reversion to the old ward-cleaning routine the epidemic of wound sepsis ended spontaneously and the number of staphylococci on the floor considerably diminished though they did not disappear

At the end of December, 1958, after a severe case of staphylococcal sepsis, an intensive campaign against wound sepsis was started The measures adopted included the use of 1/40 sudol for mopping the floor daily, wet dusting of the furniture using rags wrung out in 1/2000 chlorhexidine ('Hibitane'), and meticulous nursing techniques—which did not, however, include full isolation precautions—for infected cases Cultures were taken which showed that staphylococci almost disappeared from the floor for the next 12 weeks and during this time there was only one further case of infection

When, towards the end of April, 1959, three cases of wound infection occurred, investigation showed that the number of *Staph aureus* on the floor had again risen

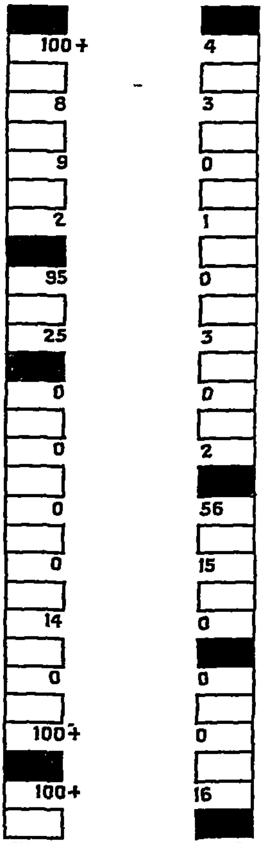

Fig 3—Numbers of *Staph aureus* per impression plate between each bed in a surgical ward Beds containing staphylococcus-infected patients in black

Discussion

From experiments in which dressings from wounds were exposed to the air, Willetts and Hare (1941) showed that large numbers of infected particles were discharged into the air Bourdillon and Colebrook (1946) extended these observations to air sampling in dressing-rooms and demonstrated that it is virtually impossible to remove dressings from an infected wound without causing airborne contamination That the air in the neighbourhood of staphylococcal carriers can be similarly contaminated during movement and other forms of agitation is illustrated by the work of Hare and Thomas (1956) and Hare and Ridley (1958)

It has always been presumed that the infected particles released into the air by these various means fall very quickly on to the floor and bedding and elsewhere, and that they are likely to remain there until the surfaces are disturbed in one way or another But this scatter has not hitherto been assessed quantitatively, and the impression-plate method goes some way to remedy this deficiency

There has been no clear evidence that *Staph aureus* infections can be airborne (Shooter et al 1958), and, even if they can, the importance of this compared with other modes of spread has not been determined One difficulty is the apparent discrepancy between the large dose of staphylococci required to produce a lesion experimentally (Elek 1956) and the small number of staphylococcus-carrying particles in the air samples The large number of organisms found in the present study on the floor near infected patients, where they may easily be rendered airborne by bedside activity before changing dressings, goes some way to resolving this inconsistency Certainly the infection of our patient who had a laminectomy wound can be explained only by airborne spread from his infected neighbour, since the sister who probed his wound was not herself a carrier

If environmental staphylococci are of some significance in cross-infection, it seems important that effective measures should be employed to keep their numbers to a minimum

Duthie (1957) found epidemic staphylococci in hospital dust and noted that when special ward-cleaning measures were introduced the bacterial population was reduced, this was followed by a reduction in wound infections Similarly, Barber and Dutton (1958) found *Staph aureus* in the ward environment at the time of an epidemic and were able to get rid of it by cleaning In contrast, Timbury et al (1958) were surprised that they could not find type 80 *Staph aureus* in a ward which had had to be closed because of epidemic infection This may have been because the ward samples were taken after the patients had been removed from the ward, for our experiment with the case of impetigo showed that, without any special cleaning process, his type of staphylococci had disappeared from the ward within 2 days of his discharge

The present study emphasises the value of disinfectants The ward-cleaning routine was not effective at first, yet, with comparatively minor adjustments, such as using a disinfectant of adequate strength and wet dusting instead of dry dusting, environmental staphylococci were reduced The experiments to determine the concentration of sudol necessary to disinfect the floor showed that it is probably unwise to be guided entirely by manufacturers' recommendations Methods of testing disinfectants in the pharmaceutical laboratory are necessarily artificial and allow enough time for the disinfectant to act on the test organism In the ward the time of contact may be much shorter, and the recommended concentration may thus be ineffective

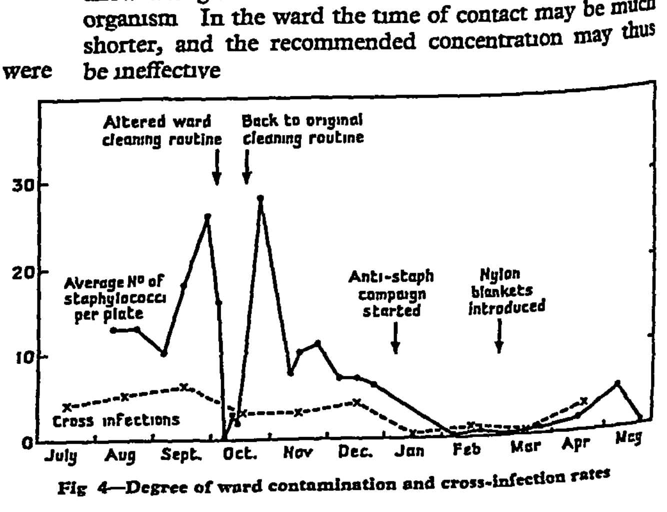

Fig 4—Degree of ward contamination and cross-infection rates

The relation between the number of environmental staphylococci and the cross-infection rate has not yet been clearly established

Shooter et al (1957) found that a high proportion of the *Staph aureus* isolated from the ward air belonged to the type causing an epidemic of wound sepsis, and suggested that the risk of an epidemic might be estimated from the number of *Staph aureus* in the air However, in a later paper (1958) they found that in a long study of staphylococci in a surgical ward several waves of colonisation of the ward with different strains of *Staph aureus* took place, and that these were not necessarily related to the incidence of sepsis

The present investigation has not continued long enough for clear-cut conclusions about this, but it provides some evidence of an inverse relation between the cross-infection rate and the number of staphylococci in the environment Counts of staphylococci, if combined with phage-typing of a random sample, might show when any strain—particularly one known to have caused an infection—was attaining dangerous proportions In the outbreak described, four out of five cases of type 77 cross-infections occurred at a time when type 77 constituted over three-quarters of the strains found on the floor The present study also indicates that one of the most important measures to combat cross-infection might be that changes of wound dressings should be confined to the period of reduced numbers of staphylococci in the ward

Summary

A new method of assessing environmental contamination by staphylococci is described, and an account is given of its use in investigating an outbreak of staphylococcal wound sepsis and in devising effective measures for disinfecting wards

I am greatly indebted to Dr J L. Pinniger and Prof R Hare for their help in the preparation of this paper, and to Dr R E O Williams for the phage-typing of staphylococci

Williams, R E O (1949) *J Hyg , Camb* 47, 416

" The welfare state has brought into existence procedures by which the natural rights of parents over their children can be encroached upon out of the highest motives Those of us who are magistrates are constantly under the temptation to assume that we know better than deviant parents and others how their children should be looked after, and social workers, too, are inclined to assume that their institutional homes are better than the apparently dreary and unattractive homes of difficult parents The powers we possess are excellent in themselves, but their abuse can lead to a new and subtle form of tyranny over an awkward minority This is most likely to happen where magistrates are keen and knowledgeable in their work and where social workers are efficient in interpreting the statutes and wishes of local authorities Thus efficiency can be its own danger in this particular field "—Mr RICHARD O'BRIEN, *The Times*, March 21, 1960, p 13

REGIONAL PERFUSION WITH CYTOTOXIC AGENTS

D B LONGMORE
M B Lond , F R C S E.

RESEARCH FELLOW, DEPARTMENT OF THORACIC SURGERY,
MIDDLESEX HOSPITAL, LONDON, W 1

CYTOTOXIC drugs, given in quantities large enough to destroy a carcinoma and allowed to get into the general circulation, may be lethal Creech (1958) and Stehlin (1958) have suggested regional perfusion as a method of delivering cytotoxic drugs in a concentration high enough to be tumourcidal, without exposing unnecessary amounts of physiologically dividing normal tissues to the drug

In this small series an attempt has been made to evaluate regional perfusion as a method of treating brain tumours and limb tumours

Two drugs were used nitrogen mustard and malphalan ester hydrochloride By careful isolation of the part it was possible to eliminate leakage into the general circulation The region chosen for perfusion was widened in some cases in order to include the regional lymphatic drainage The perfusions were carried out at 43°C (108°F) Tumour metabolism was " stepped up " by the administration of triiodothyronine for the preceding few days A high oxygen tension was maintained in the perfused parts Histamine was used to increase the capillary permeability

In all cases gravity venous drainage was sufficient A ' Sigmamotor ' pump was used to supply arterial pressure A Coolie-type stainless-steel oxygenator incorporating a heat exchanger was used It was modified to reduce its priming volume to under three pints Blood was drawn within a few days of perfusion into siliconised bottles containing 25 mg of heparin in 30 ml physiological dextrose-saline solution Patients were heparinised using 2 mg per kg body-weight immediately before cannulation ' Polybrene ' has been used throughout to neutralise the heparin in a dose ratio of 1 5 1 polybrene heparin

Technique of Brain Perfusion

Preliminary procedures were undertaken in two patients in order to establish the feasibility of total brain perfusion In these patients the carotid bifurcations, the vertebral arteries, and the internal jugular veins were exposed

The internal jugular veins were cannulated with ' Tygon ' tubing with a calibre half that of the vein These cannulæ were arranged in such manner that the venous return from the head might be diverted at will into measuring cylinders Needle Geiger counters were placed in the tips of these cannulæ. The internal carotid arteries were needled and injections of radio-isotope were made into each in turn. Thus it was possible to record the arrival and clearance times of the injected isotope at the internal jugular veins This was repeated for injections of various durations The vertebral arteries were needled and the vertebral veins compressed. Injections of radio-isotope of various durations were made into each vertebral artery in turn The arrival and clearance times of the isotopes at the internal jugular veins were again recorded by the Geiger counters The arrival-times for injections into all four vessels were 8 seconds on the ipsilateral side and 10 seconds on the contralateral side Clearance-times were less clearly marked Most radioactivity was gone from the internal jugular veins after 1 minute 10 mg batches of hot freshly prepared nitrogen mustard were then injected simultaneously into the internal carotid and vertebral arteries through the needles, which were left in situ from the injections of radio-isotope During the time when the drug could be expected to be draining through the internal jugular veins, the venous return from the head was discarded into measuring cylinders At the same time the measured loss was replaced by transfusion After the patient's blood-pressure had stabilised the injections were repeated

By this technique it was possible to give 80 mg of nitrogen mustard to the brain without leakage into the general circulation The main theoretical disadvantage of this technique was that perhaps the cytotoxic drug was not present in the brain for sufficient time to destroy the tumour Accordingly it was decided to connect the cerebral circulation to a heart-lung machine and perfuse with the cytotoxic drugs for a longer period

Both carotid bifurcations and internal jugular veins were exposed The internal jugular veins were cannulated and the cannulæ were connected through a Y tube to the venous side of the heart-lung machine The external carotid arteries were cannulated with 5 mm internal-diameter arterial cannulæ pointing downwards These cannulæ were connected by a Y tube to the arterial side of the heart-lung machine Great care was taken to exclude air from the arterial lines and connectors, to prevent embolism The vertebral veins were occluded The heart-lung machine was started, thus establishing partial perfusion of the cerebral circulation

Total perfusion was obtained by drawing tight tapes on the outside of the internal jugular veins around the cannulæ, at the same time the common carotid arteries were occluded By pumping up the operating-table to increase the suction by gravity on the internal jugular veins and increasing the output of the arterial pump, very satisfactory perfusion was obtained At all times the pressure in the carotid bifurcations was kept 10 mm below the systemic pressure in order to prevent leakage of drug into the vertebral arterial system As a result of this pressure differential the patient bled into the reservoir of the oxygenator, and a corresponding amount had to be transfused The brain was kept at normal temperature, and 30 mg of malphalan ester hydrochloride was added to the blood in the machine Within a few minutes there was œdema of the eyeballs 50 ml of 50% sucrose added to the extracorporeal circulation caused this to subside The perfusion was continued for 40 minutes The brain was then washed out with fresh blood The clamps were removed from the common carotid arteries and the venous snares released Thus the continuity of the cerebral circulation was restored The internal jugular veins were repaired after withdrawal of the cannulæ The external carotid arteries were repaired at leisure between clamps

Technique of Leg Perfusion

The legs were towelled in transparent plastic sheeting in order that changes in skin colour might be observed A nail was then driven into the greater trochanter of the femur A stout rubber tourniquet was placed around the thigh above the nail in such a manner as to leave unhampered access to the groin The femoral vessels were then exposed and cannulated It was usually possible to insert a 1 cm venous cannula into the femoral vein and a 5 mm internal-diameter arterial cannula into the common femoral artery These cannulæ were then connected to the heart-lung machine After careful aspiration of all air from the arterial line the perfusion was started The tourniquet around the thigh was now tightened Radio-isotope was now added to the extracorporeal circuit, and samples of venous blood from the arm were scanned with a Geiger counter to make certain that there was no leak from the leg into the general circulation While this check was taking place the limb was warmed to 43°C, using the heat exchanger Venous return was increased until the venous blood was well oxygenated, simply by increasing the arterial flow from the oxygenator to the limb The malphalan was then added to the arterial reservoir of the oxygenator After perfusion for 1 hour the venous blood was discharged and the leg refilled with fresh blood The cannulæ were then withdrawn, the vessels were repaired, and the tourniquet and nail were removed Postoperatively the leg was elevated to reduce œdema

Technique of Arm Perfusion

A proximal tourniquet was placed as high as possible round the arm to isolate it A distal tourniquet was placed round the wrist to exclude the hand The arterial cannula was inserted into the radial artery at the wrist, pointing proximally The brachial venæ comitantes in the upper arm were cannulated through a second small incision The arm was perfused in a retrograde manner Perfusion and flushing out were done as for the leg No attempt was made to repair the radial artery

Case-reports

Case 1 *leg perfusion* —In February, 1959, a 65-year-old woman with a malignant melanoma of the right leg was treated. The leg was covered with nodules extending to the upper thigh from a primary on the ankle 40 mg of malphalan ester hydrochloride was used There was slight postoperative œdema but no pain There has been no obvious change in the tumour

Case 2 *brain perfusion* —In June, 1959, a 37-year-old woman with left-sided cerebral metastases was treated Her right leg had been amputated on account of malignant melanoma, and brain biopsy revealed a similar tumour 30 mg of nitrogen mustard was used. A postoperative tracheostomy was done There was some cerebral œdema for 48 hours, but no significant change in her condition, and she died in the 4th week

Case 3 *brain perfusion* —In July, 1959, a 55-year-old man with bilateral cerebral and cerebellar metastases from a carcinoma of the bronchus was treated 80 mg of nitrogen mustard was used in the vertebral and carotid system Postoperatively he had cerebral œdema, which responded to intravenous sucrose and urea His general condition was made worse by the perfusion He required bronchoscopy and tracheostomy before he died after 6 weeks of bronchopneumonia

Case 4 *brain perfusion* —In September, 1959, a 50-year-old man with evidence of cerebral metastases after pneumonectomy for carcinoma of the bronchus was treated. The cerebral circulation was perfused for 1 hour using 40 mg of malphalan ester hydrochloride A tracheostomy was done Postoperatively he regained consciousness but was agitated and confused. He died suddenly at 5 hours of a massive cerebellar hæmorrhage into an unsuspected deposit

Case 5 *leg perfusion* —In November, 1959, a 37-year-old woman with fibrosarcoma of the knee was treated This knee had been arthrodesed on account of tuberculosis many years before A new swelling developed 17 months ago and was incised This had fungated Secondary nodules had appeared round it By the time the patient came for biopsy the inguinal and internal iliac glands were involved with fibrosarcoma It was decided to perfuse the limb and irradiate the iliac fossa Just as perfusion was started she had cardiac arrest requiring cardiac massage She was perfused with 70 mg of malphalan ester hydrochloride for 1 hour Postoperatively, following thoracotomy while heparinised, the patient had a hæmothorax requiring aspiration Patches of full-thickness skin loss on the leg later developed owing to overdosage of the drug She is now jaundiced and going downhill

Case 6 *arm perfusion* —In December, 1959, a 63-year-old woman, who was obese, fell at home and sustained a fracture of the left humerus Owing to the gross obesity internal fixation was required, and eventually open reduction was necessary *An unusual appearance of the fracture site prompted* biopsy, which revealed osteogenic sarcoma 3 weeks later the arm was perfused with 30 mg of malphalan ester hydrochloride Postoperatively the patient was not disturbed There is no evidence of union

HISTOLOGICAL EVIDENCE OF FAILURE

Case 1 had preoperative biopsy, operative biopsy, and serial postoperative biopsies There was no detectable change in the microscopic appearances of the tumour

Case 2 had preoperative biopsy, and at necropsy liver metastases were also sectioned The microscopic appearances

SUMMARY OF RESULTS

Case no	Region	Tumour	Result	Histology
1	Leg	Malignant melanoma	No change in tumour over 1 yr	No change
2	Cerebrum	Malignant melanoma	Died in 4th week	No change
3	Cerebrum and cerebellum	Carcinoma of bronchus	Died in 7th week	No change
4	Cerebrum and cerebellum	Carcinoma of bronchus	Died in 5 hours	No change
5	Leg	Fibrosarcoma	Patchy gangrene due to overdose	No change
6	Arm	Osteogenic sarcoma	Non-union	Not done

of the perfused brain tumour were unchanged when compared with the liver deposits and the preoperative biopsy

Case 3 had a bronchoscopic biopsy of the carcinoma of the lung Necropsy specimens showed no loss of viability of either the cerebral or the cerebellar tumour deposits

In *case 4* a specimen from the previous pneumonectomy was available. There were cerebellar deposits which were not perfused to compare with the perfused cerebral metastases There was no detectable difference between the perfused and untreated tumours

Case 5 had preoperative, operative, and postoperative serial biopsies There was no change in microscopic appearances throughout

Case 6 has not yet had post-perfusion biopsy done

The results are summarised in the accompanying table

Discussion

The work of Stehlin (1958) and Creech (1958) has shown that malphalan ester hydrochloride and similar alkylating agents do not necessarily destroy tumours in limbs Accordingly an attempt was made to enhance the activity of the drugs used, by several methods

Both the drugs used are alkylating agents, and act by chemical combination Thus it is reasonable to suppose that physical laws apply Since a 10°C rise in temperature approximately doubles the rate of a chemical reaction it was felt that perfusion at 43°C represented a satisfactory compromise between tissue damage due to over-heating and the desired acceleration of combination The heat exchanger of the machine was set at this temperature for perfusion

Histamine was added to the blood in the heart-lung machine to increase capillary permeability in order to allow greater diffusion of the drug into the tissues

These drugs are believed to act on the early stages of mitosis Therefore triiodothyronine was given to all the patients in this series for 3 days preoperatively in order to increase the incidence of mitosis

These drugs are to some extent radiomimetic. Since irradiation is more effective in the presence of a high oxygen tension, it was thought that cytotoxic drugs might act similarly In all these perfusions the arterial input to the part was increased until the venous oxygen saturation was over 80%, thus ensuring a high oxygen tension in the tissues concerned

Malphalan ester hydrochloride was used for all the perfusions except the preliminary brain experiments, for which nitrogen mustard was used because it has a shorter half-life, so that any residual drug which might have escaped into the general circulation would be less harmful

The dosage of malphalan was based on previous experience with the drug The high dosage used was aimed at approaching the maximum which normal tissues would stand 30 mg of malphalan ester hydrochloride in a brain perfusion caused cerebral œdema requiring intravenous sucrose 70 mg of the same drug caused patchy skin loss in a large leg This represents an overdose

The techniques of cannulation and running the heart-lung machine for regional perfusions are simple, though tedious Precautions have to be taken to avoid the possible complications of extracorporeal circulation, such as air or clot embolism, hæmorrhage due to heparin, pH change, temperature change, and narrowing or leakage of the vessels at the site of closure

It was found in this series that even using high concentrations of drug, and attempting to increase its efficacy, the histological appearances of the tumours treated were unchanged This was so even when normal tissue tolerance was exceeded

These results are naturally disappointing, but the history of the cytotoxic drugs is still young The techniques are established for the perfusion of limb and brain tumours When more suitable drugs are available, perfusion may represent a good method of administration Meanwhile the complications of perfusion may outweigh the palliation obtained At present, with the drugs available, perfusion may increase suffering, or even shorten life

Summary

Regional perfusion with nitrogen mustard or malphalan ester hydrochloride was applied in three cases of malignant neoplasm of a limb and three cases of cerebral neoplasm

No histological or other evidence of improvement was observed

The complications of perfusion with existing cytotoxic agents may outweigh its usefulness in the palliation of malignant conditions

I wish to thank Mr T Holmes Sellors, Mr J R. Belcher, and Dr J W Stewart for their help and support in this work, and Mr Belcher, Dr M Kremer, Mr V Logue, Mr C. J B Murray, Dr A. Jelliffe, Mr B Madden, and Mr P Wiles, of the Middlesex Hospital, and Dr O R. Garai, of the Royal Marsden Hospital, for providing patients

BLOOD-PRESSURES AFTER NEPHRECTOMY AND PARTIAL NEPHRECTOMY FOR CALCULOUS DISEASE

W J PRYN
M.B Lond, F.R C S
MAJOR R.A.M.C., SURGICAL REGISTRAR, HAMMERSMITH HOSPITAL
From the Department of Surgery,
Postgraduate Medical School of London, W 12

BY modern investigations, including divided renal function studies (Graber and Shackman 1956, Howard et al 1957, Schlegel et al 1959), aortography (Poutasse 1956, Poutasse et al 1956, Hodson 1957, Maluf 1958, Gregg 1958, Poutasse and Dunston 1958), and radioactive-diodrast renograms (Winter 1957), the significance of unilateral renal disease in patients with hypertension can be assessed. The effect of nephrectomy in such circumstances has been well recorded (Smith 1956, Thompson 1957)

Because hypertensive patients suitable for nephrectomy are usually referred to the surgeon from medical depart-

BLOOD-PRESSURES IN EIGHTEEN CASES BEFORE AND AFTER PARTIAL NEPHRECTOMY OR NEPHRECTOMY

Cases 1–6 showed a rapid, significant, and sustained fall in blood-pressure

ments, it is reasonable to assume that careful and valid blood-pressure readings will both precede and follow surgical intervention But the significance of blood-pressure readings may be overlooked when the primary indication for surgery is urological in such circumstances the preoperative blood-pressure may be interpreted as normal, whereas, in retrospect, it was relatively raised and it is the postoperative reading which is normal

Since 1952, thirty patients have undergone surgery for unilateral calculous disease of the kidney at Hammersmith Hospital In twenty-two cases blood-pressure records were adequate, but four of these patients had concomitant frank hypertensive disease This is a retrospective study of the blood-pressure of the remaining eighteen patients, who were otherwise apparently healthy but who underwent nephrectomy (fifteen patients) or partial nephrectomy (three patients) Before operation they were all considered normotensive, for their blood-pressures fell within the standard variation from the mean normal blood-pressures in relation to age (Hamilton et al 1954) Calculous pyelonephritis was later demonstrated histologically in all cases

No special methods were used to record the blood-pressures in hospital they were taken with the patients resting in bed, while follow-up readings were taken for the most part with the patients seated, though sometimes they were supine on an examination couch

The length of follow-up ranged from 7 months to 6½ years In only three cases was the follow-up less than a year (7, 9, and 9 months in cases 6, 10, and 18 respectively) Postoperative falls in blood-pressure were regarded as significant when the difference between the preoperative and postoperative mean blood-pressure was 10 mm Hg or more.

Using this criterion six of the eighteen patients showed a rapid, significant, and sustained fall in blood-pressure after operation—one after partial nephrectomy and five after nephrectomy (see table and fig 1) Five of these six patients were females, and this sex preponderance contrasts with the sex distribution of the twelve patients who showed no fall in blood-pressure after operation (fig 2)

The age-incidence of the groups of patients with and without a fall in blood-pressure was not significantly different (fig 3)

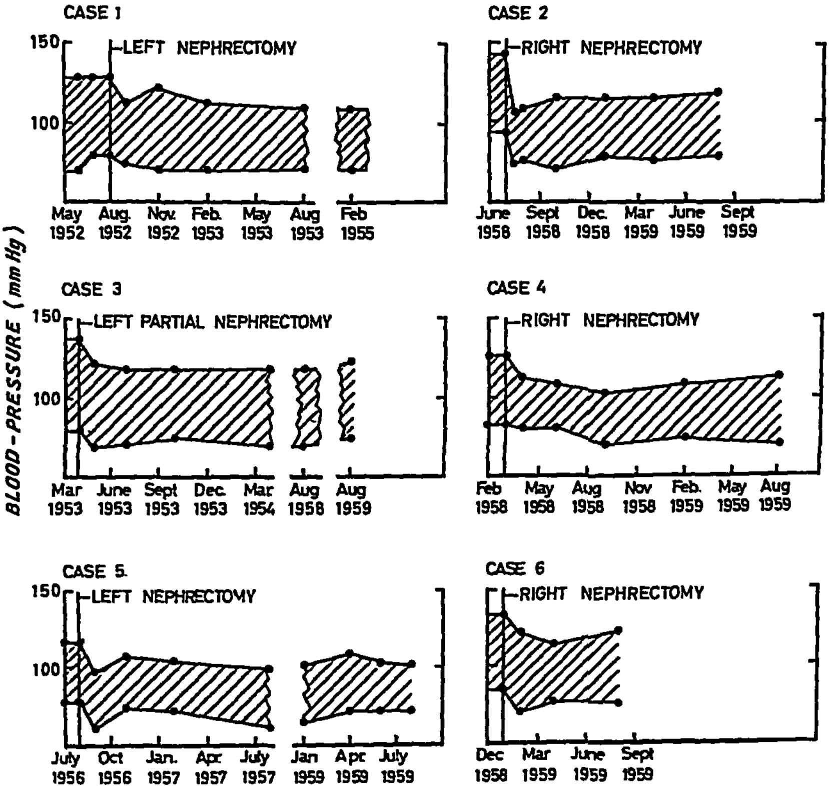

Fig 1—The six cases which showed significant fall in blood-pressure after operation The fall in blood-pressure is dramatic in onset, and sustained

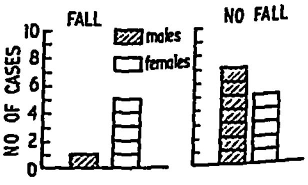

Fig 2—Sex distribution of cases which showed a fall in blood-pressure after operation compared with those which showed no fall

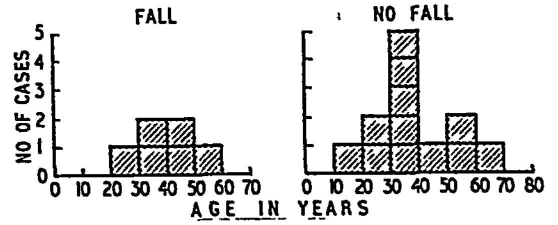

Fig 3—Age-incidence of cases which showed a fall in blood-pressure after operation compared with those which showed no fall

Histological examination of the operative specimens showed calculous pyelonephritis in all cases, but without significant histological difference between the patients with and without a fall in blood-pressure after operation

Discussion

This investigation suggests that some apparently normotensive patients who undergo nephrectomy or partial nephrectomy for unilateral calculous disease may later show a significant and sustained fall in blood-pressure, of rapid onset.

Smith (1956) recorded a significant fall in blood-pressure after nephrectomy for hypertension in 26% of five hundred and seventy-five cases of hypertension with apparent unilateral renal disease The six cases referred to in this study, who were apparently normotensive before operation but who later showed a significant and sustained fall in blood-pressure after operation, may in fact have been early cases of renal hypertension

The relation between pyelonephritis and the onset of hypertension still awaits resolution Undoubtedly chronic pyelonephritis may, on occasion, cause hypertension, and, when the disease is unilateral, removal of the diseased kidney may be followed by restitution of the blood-pressure On the other hand, some cases of chronic pyelonephritis are not associated with hypertension This study does not help to solve the problem, but it does suggest that blood-pressures which are considered normal before nephrectomy or partial nephrectomy may, in fact, be relatively raised Accurate blood-pressure observations both before and after surgery may confirm this suggestion

Summary

Preoperative and postoperative blood-pressures of eighteen apparently normotensive patients submitted to nephrectomy or partial nephrectomy for unilateral calculous disease have been studied retrospectively Calculous pyelonephritis was demonstrated histologically in all the specimens

The length of follow-up ranged from 7 months to 6$^1/_2$ years in only three cases was it less than a year

Six of the eighteen patients showed a significant, rapid, and sustained fall in blood-pressure after operation Early renal hypertension may have been present in these six cases, and the blood-pressure should be recorded accurately before and after nephrectomy or partial nephrectomy is undertaken for urological disease alone

CARCINOMA OF ŒSOPHAGUS TREATED BY EXCISION

K S MULLARD
M A, M B Cantab, F R.C.S E
THORACIC SURGEON, HAREFIELD HOSPITAL, HAREFIELD, MIDDLESEX

It has been my policy to resect and restore immediately the continuity of the gut in all patients presenting with carcinoma of the middle or lower third of the œsophagus, and of the cardia—excluding only those with obvious metastases, and those whose general condition precluded any prospect of their surviving the operation This policy was adopted about 12 years ago because the symptoms from these conditions, untreated, make life intolerable, because without treatment the prognosis is invariably hopeless, because no other form of treatment gave so much symptomatic relief, and because excision of the growth offered some prospect of permanent cure As the years passed, my experience, and that of others (Ravitch et al 1952, Garlock and Klein 1954, Sweet 1954), showed that few patients survived long, and the general impression of the results of œsophageal resection was gloomy But even so, resection of the primary growth and immediate restoration of continuity seemed well worth while in view of the symptomatic relief which it gave

Then, in 1956, Mousseau et al introduced a permanent indwelling plastic tube with which dysphagia could be very greatly, though not entirely, relieved Experience with this tube (Moghissi 1960) has shown that much relief can be obtained at a low operative risk With this technique available it was clearly no longer justifiable to expose patients to the severe operative risks of resection, unless some additional advantage might be gained, either by increasing the expectation of life or by giving greater symptomatic relief The results of treatment by excision were therefore reviewed, and are set out below

The Series

The series comprised one hundred and forty patients, of whom forty were women, seen between 1948 and 1958 The average age at the time of diagnosis was 65, ranging between 39 and 85, one hundred and two were over 60, fifty-one were over 70, and ten were over 80 These figures show that it is not realistic to look for the customary 5-year survival in a group of patients of whom half have already reached the normal expectation of life for this country—67 years—at the time of diagnosis, and another quarter are within less than 5 years of it Three main operative procedures were used

Ivor Lewis Operation

For growths of the middle or lower third of the œsophagus, with the exception of those at the extreme lower end (last 2–3 cm) the Ivor Lewis operation (Lewis 1946) was employed

Through an upper paramedian incision the stomach is freed of its mesentery and all its vascular attachments, with the exception of the right gastroepiploic artery The abdominal incision is closed, and, through a right thoracotomy, the thoracic œsophagus is excised, continuity being restored by drawing the stomach into the chest and anastomosing it to the œsophagus at the apex of the chest

Forty-five cases fell into this group The growth was an adenocarcinoma in five cases, polygonal in one, undifferentiated in one, and squamous in the remainder Of this group, ten patients died within a month of operation, twenty-four died within a year of operation, three died within 18 months, and one died 2$^1/_2$ years, and another 3$^1/_2$ years, after operation

Five are alive 18 months, 20 months, $4^{1}/_{2}$ years, 6 years, and $6^{1}/_{2}$ years after operation One has been lost sight of

Thus five out of forty-five lived more than 2 years

Gastrectomy

The second operation used was total gastrectomy for growths of the extreme lower end of the œsophagus and cardia

Through a left thoracoabdominal incision the entire stomach, the lower third or quarter of the œsophagus, the spleen, and the body and tail of the pancreas are resected in the extraperitoneal plane Continuity of the gut is restored by œsophagojejunostomy, either end-to-side with enteroenterostomy between the arms of the jejunal loop, or by the Roux-Y technique This procedure is on the lines described by Allison and Borrie (1949)

This group comprised twenty-three patients Thirteen had adenocarcinomas, four had squamous-cell carcinomas, three had polygonal-cell carcinomas, two had columnar-cell carcinomas, and one had an undifferentiated carcinoma Of these patients, eight died within a month of operation, six died within a year or less, two died within 18 months, one died after 4 years, and one after 4 years and 8 months Four are alive 15 months, $5^{1}/_{2}$ years, 7 years, and $7^{1}/_{2}$ years after operation

Thus roughly a third died from operation, another third died within 18 months, and over a fifth survived 4 years or more, three being still alive more than 5 years after operation

Œsophagogastrectomy

Early in the series, before its disadvantages were known, and later on, but then only for technical considerations, a lesser procedure than total gastrectomy was used for growths of the lower end of the œsophagus and cardia This was excision of the lower third of the œsophagus and upper half of the stomach, with restoration of continuity by œsophagogastrostomy

This group also comprised twenty-three patients The pathological types of tumour were about equally divided between squamous carcinoma and adenocarcinoma, with a few columnar-cell and undifferentiated carcinomas Six of these patients died of operation, eleven died within the 1st year, and four within the 2nd year One lived over 7 years, and another is alive 4 years after operation.

Thus only two of this group have survived more than 2 years

Miscellaneous Procedures

A fourth group, comprising a miscellany of forty-nine patients, shows the extremely poor outlook in patients to whom no radical treatment can be given

Seven were explored by laparotomy or thoracotomy and found hopelessly inoperable, all died within 6 months, and most within a few days or weeks Eight had bypass operations, usually in the form of a Roux-Y œsophagojejunostomy, the primary growth being irremovable, one of these patients lived a year, and the others died within 6 months Eleven were treated by intubation with Souttar's tube on one or more occasions, one lived for a year, and one for 6 months, and the others died within a few weeks In ten cases, diagnostic œsophagoscopy only was performed, none lived more than 4 months Eight had radiotherapy Two patients with growths of the upper third of the œsophagus were treated by total resection of the thoracic œsophagus, followed by cervical œsophagogastrostomy, both died within 4 months of operation One patient with carcinoma of the middle third of the œsophagus was treated by local excision and end-to-end œsophago-œsophagostomy, she lived 14 months One patient was intubated with a plastic tube, and another refused all investigation and treatment, both died within 2 months

RESULTS OF TREATING CARCINOMA OF ŒSOPHAGUS

Type of growth and operation	No of cases	No surviving after operation			
		1 mo	1 yr	*18 mos*	2 yr
Ca of middle and lower thirds, treated by Ivor Lewis operation	45	35	13	9	5
Ca of extreme lower end of œsophagus and cardia, treated by total gastrectomy (Allison)	23	15	10	7	5
Ca of extreme lower end of œsophagus and cardia, treated by excision and œsophagogastrostomy	23	17	7	4	2
Miscellaneous cases, treated by intubation, bypass, &c, or untreated (excluding those treated by radiotherapy) *	41	29	4	0	—

* In this group, many of which were inoperable, survival periods are calculated from the time of diagnosis

The results of radiotherapy are not within the scope of this article, and in any event the number of cases is small But my experience confirms the generally accepted view that carcinoma of the upper third of the œsophagus responds satisfactorily to radiotherapy but growths of the middle and lower thirds do not

Discussion

Of the hundred and forty patients with dysphagia due to malignant disease, a hundred and eight had a major surgical operation Of these, ninety-three had resection of the growth with immediate restoration of continuity, eight had a bypass operation, and seven a laparotomy or thoracotomy only Of the resections, ninety-one were for growths of the middle or lower thirds of the œsophagus and cardia

The table shows the results in these ninety-one patients For growths of the middle and lower thirds, rather fewer than a quarter died as a result of operation, and rather more than a tenth survived for 2 years or more For growths of the lower end of the œsophagus and cardia for which total gastrectomy was used, a third died as a result of operation, and more than a fifth survived for 2 years or more, but when local resection was used, although the operative mortality fell from a third to a quarter, the 2-year survival prospect fell from a fifth to less than a tenth Few patients survived long when local resection was used, and the results of operation were poor

Local resection leads to local recurrence of the growth at the site of the œsophagogastric anastomosis, and with this recurs the same distressing dysphagia which characterised the disease at its onset In addition the symptoms of a diaphragmatic hernia of stomach are produced, and these are far more troublesome when part of the stomach lies immediately above the diaphragm than they are after the Ivor Lewis procedure in which the entire stomach is drawn well up into the chest Local resection has been abandoned, therefore, as a planned procedure Intubation by the Mousseau-Barbin tube is likely to relieve the symptoms equally well, and with a far lower immediate mortality

The Ivor Lewis and Allison operations are far more satisfactory It is true that only a ninth of the patients survive the Ivor Lewis operation for more than 2 years, but after an initial period of adaptation, those who survive can usually take an almost normal diet, both liquid and solid, with enjoyment If the growth recurs, it seldom does so at the site of anastomosis, hence the final demise usually results from distant metastases, which is a kinder process In the

Allison operation, a fifth of the patients survived for 2 years or more—a far from hopeless prognosis The period of adaptation to an œsophagojejunostomy is longer and more difficult than is the case after the Ivor Lewis operation, and considerable dietary restriction is usually required permanently, but this is not an unduly high price to pay for the prospect of long survival Both operations, besides offering long survival, provide far greater symptomatic relief than can ever be obtained by intubation, where the patient is always restricted to an almost fluid diet

Although the results of these major operations are marred by high operative mortality, this arose very largely in the first cases of the series when the operations were new and untried, and the complexities of technique and postoperative care were poorly understood The present operative mortality is far lower, and in the future the figures should be lower still Many authors, such as Collis (1957), have separated their earlier cases from their series, to show the present position

Summary

Experience with a hundred and forty cases of œsophageal carcinoma between 1948 and 1958 suggests that the Ivor Lewis and Allison operations, for resection of growths of the middle and lower thirds of the œsophagus and cardia, offer good symptomatic relief and a prospect of long postoperative survival

Less extensive resections and bypass operations give poor results, and they should be abandoned in favour of intubation by plastic tubes of the Mousseau-Barbin type

PALLIATION IN MALIGNANT STRICTURE OF THE ŒSOPHAGUS

K Moghissi
M D , M S Chir Geneva
SENIOR REGISTRAR IN THORACIC SURGERY, HAREFIELD HOSPITAL, HAREFIELD, MIDDLESEX

ŒSOPHAGECTOMY and re-establishment of the continuity of the digestive tract is the treatment of choice for malignant œsophageal stricture But not all patients can benefit from œsophagectomy, many are regarded as inoperable owing to extensive growth, advanced age or poor general condition In these "inoperable cases", however, relief from dysphagia by some palliative method should always be considered

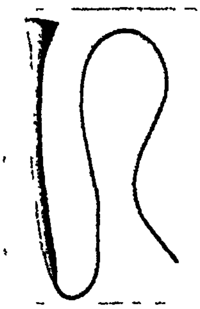

Fig 1—The Mousseau-Barbin tube

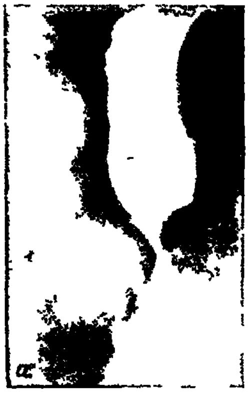

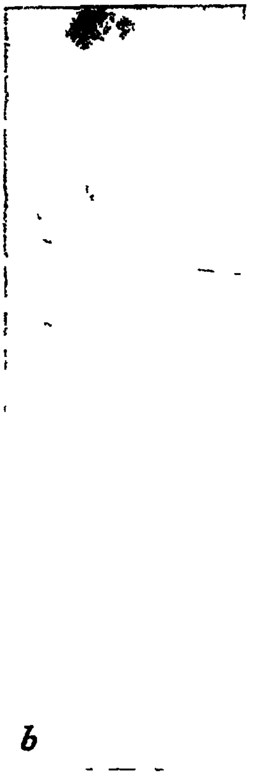

Fig 2—(*a*) Barium-swallow in case 5 showing stricture of œsophagus and (*b*) the same case after insertion of the Mousseau-Barbin tube, showing the position of the flange above the stricture and of the cut end above the cardia

Gastrostomy, once so popular, is a very unkind and unsatisfactory procedure, for, when food is put directly into the stomach its taste and the enjoyment of it are lost, and considerable discomfort, due to inability to swallow saliva, remains

Many different procedures are used to bypass the growth by means of a transplant of small or large bowel, or to maintain patency by inserting one of the many indwelling tubes designed for this purpose

I should like to describe a method used in the thoracic surgical unit at Harefield Hospital in seven cases of inoperable malignant stricture since November, 1958 (see table) Although the number of patients is small, the

PATIENTS WITH SEVERE DYSPHAGIA TREATED WITH MOUSSEAU-BARBIN TUBES

Case no	Sex	Age (yr)	Diagnosis	Histology	Level of stricture	Results
1	F	74	Carcinoma of œsophagus	Squamous-cell carcinoma	Middle third	Dysphagia relieved, died of bronchopneumonia 4 weeks after operation
2	F	82	" "	" "	Lower third	Dysphagia relieved, swallowing well 40 weeks after operation
3	M	41	Carcinoma of bronchus	" "	Middle third	Dysphagia relieved, died of ? rupture and hæmorrhage caused by tube 8 weeks after operation
4	F	78	Carcinoma of œsophagus	" "	" "	Dysphagia relieved swallowed well for 17 weeks then died from general weakness
5	M	74	" "	" "	" "	Swallowing well 10 weeks after operation
6	M	75	" "	" "	" "	Swallowing well 8 weeks after operation
7	M	55	Carcinoma of bronchus	Oat-cell carcinoma	" "	Swallowing well 10 weeks after operation

results have been good We shall therefore continue to use the method ourselves, and we recommend it to others for suitable cases

Cases and Treatment

Five patients had carcinoma of the œsophagus which caused very severe dysphagia In the other two dysphagia was due to involvement of the œsophagus by an inoperable bronchial carcinoma

Method of Treatment

The method is based on that of Mousseau et al (1956)

These workers use a special catheter (the Mousseau-Barbin tube) of 'Neoplex' plastic This tube is 30 cm long and has a diameter of 10, 12, or 14 mm, its upper end is funnel shaped, and the lower end continues as a tail 5 mm in diameter and 70 cm long, resembling a Ryle's tube (fig 1)

The catheter can be inserted in various ways We use a variant of the designers' method, as follows

1 A gum-elastic bougie is passed through the stricture into the stomach via an œsophagoscope The œsophagoscope is then removed leaving the bougie in situ.

2 Laparotomy is performed through a small upper midline abdominal incision, and, after inspection of the intraperitoneal viscera, a fairly high gastrostomy is done, through which the end of the bougie is grasped (If there is difficulty in introducing the bougie from above, it can be pushed up via the gastrostomy opening and the cardia to reach the mouth)

3 The tail of the catheter can next be attached to the mouth end of the bougie, which is drawn out through the gastrostomy opening so that the end of the Mousseau-Barbin tube appears in the stomach

4 By pulling out the end of the tube through the gastrostomy opening, the catheter proper gradually enters the œsophagus, some resistance is felt when it passes the pharyngo-œsophageal junction, and especially when it enters the stricture

5 The position of the funnel-shaped flange of the catheter should be adjusted so that it lies just above the stricture This is best done from above, by direct vision through the œsophagoscope

6 The excess tube protruding through the gastrostomy is cut off as high in the stomach as possible (The cut end often retracts to a position above the cardia) (Fig 2b)

7 The gastrostomy is closed and the abdominal wall repaired

We find that the operation is very much simplified if one member of the team carries on the œsophagoscopy and all the manipulation from the mouth, while another prepares the gastrostomy, then, with close cooperation, the tube can be inserted in the exact position required (fig 2a and b)

Postoperative Management

For the first 24–48 hours after operation the patient should be given only fluids, thence progressing gradually to more solid food Some patients may have slight regurgitation for a day or so, but this soon responds if the patient is nursed in Fowler's position and got out of bed as soon as possible

Results

The table summarises the results My colleagues and I have been impressed by the immediate relief of dysphagia, the simplicity of the operation, and the low operative mortality In those cases with œsophageal stricture which is unsuitable for resection this seems to be a great improvement upon other palliative measures

I should like to thank Mr K S Mullard for permission and opportunity to publish this paper, and Mr K S McDonald, photographer at Harefield Hospital, for reproducing the figures

The Mousseau-Barbin tube is made by Messrs Porges, Paris, France

AGRANULOCYTOSIS AND SEPSIS ASSOCIATED WITH PREDNISOLONE

R Rokseth
M D Oslo
ASSISTANT PHYSICIAN

From the Department of Medicine,
Nordland County Hospital, Bodö, Norway

HÆMATOLOGICAL side-effects during corticosteroid therapy are rare Stevens and Toone (1952) and Toone and Irby (1955) mention 3 cases of leucopenia after cortisone injections It is not clear whether the leucopenia was caused by cortisone itself or by some vehicle in the preparation Heck (1956), however, includes cortisone among drugs which may cause leucopenia Snively et al (1953) mention a case of aplastic anæmia occurring after corticotrophin injections Animal experiments indicate an adverse effect of cortisone on bone-marrow regeneration after X-radiation (Thiersch et al 1952)

This paper reports agranulocytosis and sepsis in a patient after oral administration of prednisolone We have not been able to find any similar cases described previously

Case-report

A woman, aged 64, was in March, 1956, examined in hospital because of a moderately elevated sedimentation-rate, which had persisted for at least 3 years No cause was found. The blood smear and the sternal marrow were normal

In October, 1956, she received radiotherapy of the cervical spine for spondylarthrosis She had during the previous 11 years received 3 series of therapy to the lumbar spine, and 2 to the cervical spine, totalling about 3000r *

In March, 1957, erythema multiforme developed on both arms without any apparent cause She was given prednisolone, 5 mg three times daily, decreasing to 5 mg daily After a few relapses the eruptions ultimately disappeared in 3 or 4 weeks She continued, however, taking the tablets "to be on the safe side"

2 weeks later urticaria developed on the chest and abdomen. She felt ill and had a sore throat. Prednisolone was discontinued and the urticaria disappeared. Her general condition, however, deteriorated and she was admitted to hospital a week later with fever, pallor, weakness, and a purulent stomatitis Clinical findings were otherwise normal

Blood investigations—Hb 9 1 g per 100 ml, red cells 3,600,000 per c mm, white cells 500 per c mm., platelets 175,000 per c mm A blood-smear showed no polymorphs, only lymphocytes The sternal marrow revealed normal erythropoiesis and thrombopoiesis, but in the granulopoiesis a maturation arrest at the stage of promyelocytes A profuse growth of pyogenic staphylococci was cultured from the blood.

She was treated with erythromycin ('Ilotycin') and blood-transfusions, and the fever subsided in 3 days The white-cell count, hæmoglobin, blood-smear, and sternal marrow were normal after 10 to 12 days Scratch tests with a prednisolone solution were negative She had taken no other drugs

---

* Irradiation given with filter $^1/_2$ Cu, tube-skin distance 40 cm, 170 kV and 6 mA Applicator size 10 × 24 cm lumbar spine and 10 × 15 cm cervical spine

Clinical findings and blood-counts were normal 2 years later The sedimentation rate was 30 mm per hr

Discussion

Agranulocytosis is usually due to drugs The first symptoms in our patient, a sore throat and urticaria, appeared while she was taking prednisolone, and this synthetic corticosteroid was the only drug she had taken The urticaria disappeared when prednisolone was discontinued and her condition improved with antibiotic therapy This reinforces the supposition that prednisolone was responsible It may seem paradoxical that an antiallergic drug could cause agranulocytosis, but agranulocytosis may also follow the giving of antihistamines (e g , Blanton and Owens 1947, Hilker 1950, Drake 1950)

Other possible causes of leucopenia must be considered (1) earlier radiation therapy, (2) possible underlying disease, (3) sepsis

(1) Blood and marrow changes after radiation comprise the acute changes during the first weeks after exposure, and the late changes that appear gradually, months to years, after radiation (Medical Research Council 1956) While the acute damage may be reversible, the late changes, such as leukæmia and aplastic anæmia (Court-Brown and Doll 1956), seem to be irreversible (Hollaender 1954) According to present knowledge there is little reason to believe that acute agranulocytosis, with rapid complete restitution, can be caused by local routine radiotherapy several months or years earlier

(2) The leucopenia during some diseases (measles, typhoid fever, &c) is not as severe as in our case (Wintrobe 1956) Besides, clinical and laboratory examination did not reveal any underlying disease at the time of agranulocytosis or during controls up to 2 years later The patient had evidently recovered from the original skin disease since no signs of erythema multiforme recurred

(3) Sepsis may occasionally be accompanied by leucopenia, and severe infections may occur during corticosteroid therapy (Shaper and Dyson 1955, Slaney and Brook 1958) Wintrobe (1956), however, maintains that in patients with agranulocytosis and sepsis, the sepsis is to be regarded as secondary

Summary

Agranulocytosis and sepsis developed in a woman of 64 who had been treated with prednisolone for erythema multiforme There are reasons for believing that prednisolone was the cause

I am grateful to Dr Ole Storstein, former head of the department of medicine, Bodö Hospital, for his advice

Preliminary Communication

PARABIOSIS INTOXICATION SYNDROME IN MICE

WE here report the development in parabiosed homologous mice of a condition resembling that known as the parabiotic intoxication syndrome of rats, first described by Ranzi and Ehrlich [1]

We chose for parabiosis young adult female C3H and AKR mice, using a modification of the technique of Bunster and Meyer,[2] in which we did not incise the abdominal wall but merely sutured the flank muscles of the two animals together just below the costal margin. Excluding variable mortality in the first three postoperative days which was attributable to operation and to malnutrition due to mechanical difficulties of eating and drinking, the mortality was very low until the seventh day In about 75% of the pairs which survived, however, one or both animals of a pair died between the seventh and fourteenth days The peak mortality was at twelve days 9 out of 53 pairs survived twenty-one days or longer, and of the pair which survived longest the AKR mouse died on the fifty-sixth day In the pairs where only one mouse died, this was more often the AKR mouse.

The animals all became wasted, with roughening of their coats and loss of hair, but this was much worse in the AKR mice than in the C3H mice These changes were not due to parabiosis, since pairs of AKR or pairs of C3H mice gained weight and had normal coats

Pallor of the AKR mice attracted our attention, hæmoglobin studies revealed anæmia in all AKR mice, with hæmoglobin values under 6 0 per 100 ml and normal or raised values in the C3H mice. In 61% of the C3H mice the hæmoglobin level exceeded 18 0 per 100 ml In isologous parabiotic pairs, the mean hæmoglobin level was 14 4 per 100 ml (S D 1 8)

White-cell counts showed comparable changes The majority of AKR mice showed a profound leucopenia with values sometimes as low as 500 cells per c mm., whereas the C3H mice showed normal or slightly high counts

The similarity between the parabiosed mice and previously described "red" and "white" parabiosed rats [3] [4] is striking The mechanisms involved have still to be determined But the constancy and degree of anæmia and leucopenia in the white mouse suggest that some mechanism is responsible for the parabiosis intoxication syndrome other than that postulated by Hall and Hall [4]—namely, that one animal develops anæmia because of loss of blood to the other member of the pair This is being investigated further

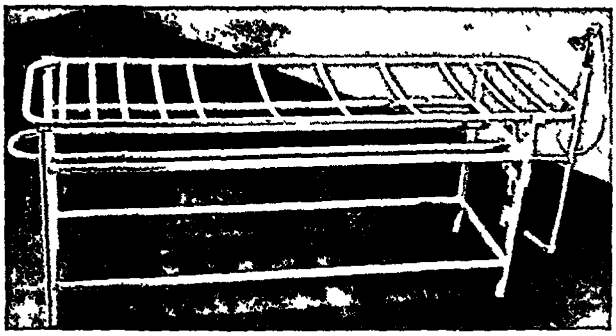
New Inventions

A TABLE FOR TREATING HEATSTROKE

THE essential principle in treating heat stroke is to cool the patient's body as rapidly as possible Recommended methods employ one or other of two principles—convective cooling (the patient being immersed in an ice-cold bath) or evaporative cooling (the patient being wrapped in a wet sheet) Cooling by convection and evaporation simultaneously is an obvious advance A treatment table designed for this purpose is shown in the figure The table is so constructed that water can be sprayed from above and below at the same time The top of the table is made of slats, between which water is directed upwards on to the patient's back, and water is also sprayed from above by a hand shower Thus almost the whole skin surface of a patient can be cooled

Cooling is achieved partly by heat exchange from the hot skin to the cold water, and partly by evaporation of water from the skin surface The water acts as "artificial" sweat, for the patient's own sweat secretion has invariably ceased in heatstroke The room in which the treatment table is housed must be well air-conditioned and fitted with a powerful ceiling or wall fan so that the patient can be exposed to a current of cool dry air to enhance evaporative cooling

The table is 7 ft. long, 2 ft 6 in wide, and 3 ft high The frame is made of simple 1 in galvanised iron piping The slats of the upper surface are 1 in aluminium strips set at 10 in centres, with two extra slats at the head and one at the foot set at 5 in centres The closer setting at the ends provides more support for the head and feet, whilst the more open setting in the middle allows greater exposure of the skin of the back to the lower spray The slats are welded to the piping at the edges The $^3/_4$ in pipes of the lower spray are set 6 in below the slats Water is delivered through $^1/_{16}$ in perforations set 2 in apart (5 between each pair of slats) and countersunk $^1/_{32}$ in to produce a spray rather than a jet The upper spray is an ordinary hand shower with a flexible metal hose and rose, as commonly fitted to domestic baths



Chilled water, ideally at a temperature of 45°F (7°C), is delivered to the sprays at a pressure of 40–45 lb per sq in through T-pieces which reduce from 1 in to $^3/_4$ in In Kuwait the chilled water comes from one of three sources

1 A 6-in chilled-water main serving a central air-conditioning plant, this circulates at 42–45°F (6–7°C)

2 A small 3–5 h p 'Freon' refrigeration unit The cold water produced is stored in an insulated 400-gal tank which ensures an adequate supply at about 42–45°F

3 A 15–20 h p freon refrigerating unit which cools water directly as it passes through

Tables of this type have been in use in our hospital for the past eleven years and have been very satisfactory Rectal temperatures may be reduced by this means from 106–110°F to 102 F within twenty to thirty minutes

We wish to thank the Kuwait Oil Company management for permission to publish this account, Dr Charles Leithead, of the Liverpool School of Tropical Medicine, for much assistance, and Mr L D Reeves, of the Kuwait Oil Company engineering department for having the table made

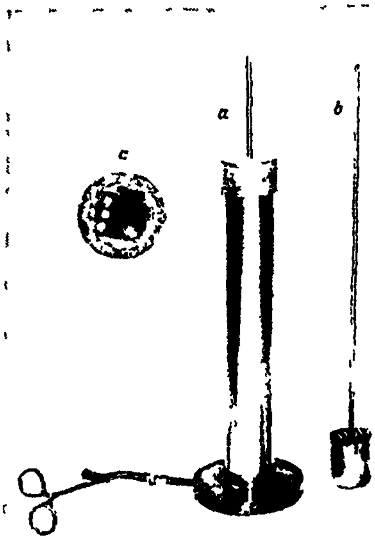
A SIEVING DEVICE FOR PREPARING BONE-MARROW FOR INTRAVENOUS INFUSION

THE material aspirated by multiple bone-marrow puncture comprises marrow particles, fat, and blood, though much of the marrow is intimately mixed with the fat McFarland and Mathé[1] have transfused such material intravenously immediately after aspiration without harm, but if transfusion is delayed beyond a few minutes, and particularly if low-temperature storage is employed, the fat solidifies and much of the myeloid tissue is trapped Since the solid fat cannot be resuspended, transfusion of the material in this condition would be hazardous, and removal of the fat would involve loss of many marrow-cells Donnall Thomas[2] overcame this difficulty by passing the marrow repeatedly through sieves of decreasing pore size, and then separating the fat by gentle centrifugation. Very few cells are lost in the fat layer, and this technique has the added advantage of reducing the size of the larger cell clumps

My apparatus has proved more convenient than other sieving syringes, and its use makes for greater speed and sterility than did previous techniques

The marrow is aspirated into syringes containing a little heparinised tissue-culture fluid, and delivered into a siliconed 540 ml transfusion bottle Using non-wettable polyvinyl-chloride tubing (detached from a disposable recipient set), the suspension is transferred to a siliconed stainless-steel cylinder 10 in high and of $1^3/_4$ in bore, through a Luer inlet at the base The rubber segment of the inlet tube is then occluded with artery forceps (see figure) Two pistons, also siliconed, are provided to fit snugly into the cylinder, one is shown in the cylinder (*a*), and the other outside (*b*) Each piston is constructed as a hollow cylinder and its lower end is closed by steel gauze—40 mesh for the coarser sieve, and 200 mesh for the finer sieve The lower surface of the piston with the coarser sieve is seen in the insert (*c*) The sieves have pore apertures of 380 μ and 80 μ The marrow suspension is sieved several times with the coarser piston, and then with the finer piston At the end of this process the marrow is returned through the tubing to the original bottle to be centrifuged Afterwards the fat and most of the heparinised supernatant fluid are aspirated through a wide-bore needle



The suspension is transferred between the bottle and the cylinder by gravity, assisted when necessary by moderate positive or negative air-pressure applied to the bottle The device handles 200–250 ml of fluid at a time It has an aluminium cap, perforated to take the piston handle, and a heavy brass base Otherwise it is constructed entirely of stainless steel The apparatus may therefore be sterilised in an autoclave All internal surfaces are treated with 'Midland' silicone (M S 1107) cured at 150°C for 15 minutes

Vol XV *Urology in Childhood* D INNES WILLIAMS, M.D, M.CH, F R.C.S, surgeon, St Peter's and St Paul's Hospitals, genitourinary surgeon to The Hospital for Sick Children, Great Ormond Street, London Pp 353 DM 118

THE idea of an Encyclopædia of Urology in 16 volumes (each published separately in English, French, and German) providing a standard international work of reference is something exceptional in a specialty of medicine The editors, from Great Britain, Germany, Switzerland, and the U S.A, have set out to compile a mass of authoritative information on all aspects of urology, and they have the aid of well-informed and experienced urologists The three volumes now available reflect the wide range of the work and the broad geographical distribution and international repute of the authors There is little doubt that the complete encyclopædia will ultimately rank as a reference work without equal

Volume VI is a compact and comprehensive guide to urological endoscopy, giving details of the wide range of instruments available and their use in diagnostic and surgical procedures Of particular merit is the orderly sequence in the description of endoscopic methods and the interpretation of the appearances of the lower urinary tract in health and disease These appearances are profusely illustrated in colour and half-tone The second half of this volume is concerned with endoscopic surgery and contains valuable information on training in this specialised art, details of the equipment and electrical apparatus required, and of the various indications for its use. The technique of endoscopic prostatic resection with the Stern-McCarthy electrotome is fully described, but little space is given to the cold-punch procedure, which is not illustrated.

Volume IX/2 deals with tuberculosis, parasitic infestations, and certain forms of venereal disease Ljunggren gives a masterly description of urogenital tuberculosis, its modification by chemotherapy, and the present scope of surgical treatment, based on a wide personal experience and supplemented by that of other well-known authorities Campbell-Begg gives an exhaustive account of parasitic disease, from vegetable and protozoan invaders to a solitary lower-vertebrate intruder This fascinating study, embracing schistosomiasis, hydatid disease, and various helminth infestations, set against a full background of comparative zoology, must be unequalled in urological literature King's third section is about specific types of venereal infection including syphilis, lymphogranuloma venereum, granuloma inguinale, and chancroid. Each is considered particularly in terms of diagnosis and effective treatment and useful descriptions are given of the appropriate confirmatory tests and modern methods of chemotherapy Gonorrhœa is discussed in volume IX/1

Volume XV deals with urology in childhood, a specialty within a specialty, which has been exceptionally developed in Great Britain, so it is fitting that this volume was entrusted to Innes Williams, whose embryological research and work on the structure and dynamics of the urinary tract in childhood have attracted international attention. As he points out, with the general advance of pædiatric and preventive medicine, acquired disease is becoming rarer and congenital abnormalities consequently provide a large part of the urologist's work and occupy much of this book. There are also important sections on enuresis and the neurogenic bladder, and on the variations exhibited in childhood by such conditions as lithiasis, inflammatory disorders, and neoplasia, which are perhaps more familiar in adult life This admirably balanced volume ends with a comprehensive study of intersex and endocrine disorders

Each volume on its own merit is an outstanding contribution to the study of urology To some British readers the format may seem strange, for no separate chapters are discernible, but an excellent index and ample references resolve this difficulty

Growth Diagnosis

LEONA M BAYER, associate clinical professor of medicine, Stanford University School of Medicine, NANCY BAYLEY, chief, section of child development, National Institute of Mental Health Chicago University of Chicago Press London Cambridge University Press 1960 Pp 241 80s

THIS book is an attempt to provide the pædiatrician with a guide to useful procedures in assessing the growth and development of children under his care. The authors assume familiarity with the basic facts of growth and do not attempt to record them here. They describe how to measure height, weight, sitting height, and biacromial and bi-iliac diameters, how to take front, side, and rear view body photographs, how to use the Greulich-Pyle skeletal-age atlas, and how to plot the anthropometric values on charts and tables Some of the methods they advocate are not those now thought best The standard tables date from 1931, and so, by the looks of things, does the instrument for measuring hip width In charting weight deviation in terms of standard deviations rather than percentiles, the authors will have few supporters, but they break new and interesting ground in providing charts for height and weight against age which allow for advancement and retardation in maturity

The last two-thirds of the book is occupied with descriptions of 8 normal children and 22 children with growth disorders These are of much interest, they are very well illustrated and often the children are followed over long periods of time with body measurements, photographs, and skeletal age determinations Dr Bayley's method of predicting adult height from age and skeletal maturity is fully tested and emerges very creditably indeed even from this trial by pathology This is a book for pædiatricians to ponder over, and for others (not least, since the layout is excellent, those contemplating publishing) to glance through It invites criticism in detail but deserves nothing but praise in intention and general outline

Fundamental Techniques of Plastic Surgery

IAN A MCGREGOR, F.R C S, F R.F P S, plastic surgeon, Glasgow Royal Infirmary Edinburgh E & S Livingstone 1960 Pp 244 30s

THIS volume is in two parts the first section of 141 pages deals with basic techniques of plastic surgery, and the second explores certain clinical applications The exposition of basic techniques is almost wholly confined to problems of skin cover, and within these limits it is excellent, the text is clear, the drawings are helpful, and the photographs of favourable results are very encouraging Mr McGregor gives detailed attention both to surgical technique and to the special instruments appropriate to plastic surgery He discusses fully such matters as keloid formation, the use of the Z-plasty, the factors governing the " take " of free grafts, and the scope and management of skin flaps and tubed pedicles

The second part of the book contains a chapter on general surgery, which deals with methods of skin repair of lips, limbs, scalp, breast, and anus, and the minor role of grafting in the treatment of leg ulcers is outlined Skin problems in orthopædic cases, eyelid repairs, and hand injuries are also discussed. But the casualty surgeon, as well as the surgeons in other specialties for whom the book is designed, will find no information on such matters as acute fractures of the malar bone or the nose, or the treatment of any congenital deformity, and well-tried plastic procedures involving the use of epithelial inlays, fascial grafts, bone grafts, cartilage grafts, and fat grafts are not discussed It is strange that these important matters are excluded, while methods of reconstructing of the eyelids are elaborately described and illustrated

The index lacks some important headings, including " bone ", " fracture " (except finger), " palate ", " jaw ", and " burns " *The reader's difficulty in finding what he wants is aggravated* by the decision to exclude all eponyms, and many surgeons will not easily recognise the familiar Abbe flap disguised as the " V-lip-switch-flap "

With these reservations this is a well-produced book.

Public Health in the Town of Boston 1630-1822

JOHN B BLAKE Cambridge, Mass Harvard University Press London Oxford University Press 1959 Pp 278 52*s*

THE main purpose of this book is to study the effects of imported infectious diseases, mainly smallpox and yellow fever, on the history of Boston Smallpox reigned supreme among the epidemics of the eighteenth century It flourished in all climates, it could be diagnosed with reasonable certainty, and it was the main battle ground between those who attributed the spread of infection to contagion and those who blamed " the depraved constitution of the atmosphere " In the face of smallpox the contagionists won easily, but yellow fever set problems which were not solved until much later (It is usually assumed that in a place so far north as Boston yellow fever was spread by *Aedes ægypti* imported in the bilges and water-butts of ships coming from ports where the disease was rampant Is it possible that some native vector took its place?) In Boston the struggle between those who favoured inoculation against smallpox and those who feared—with some reason—that the practice would spread the disease was prolonged, as in London, until the introduction of vaccination This book makes it clear that inoculation was largely the privilege of the rich. In contrast the most striking thing about Jenner's discovery was the speedy dissemination of the new knowledge and its immediate acceptance Besides the prevention of infectious disease brought from elsewhere, the other continuous care of the town authorities—and alien readers would have valued a short account of the organisation of local government—was the cleaning of the streets and the disposal of offensive wastes It was good work usually done for the wrong reasons

These are interesting topics, but, though this book adds a lot to our knowledge of the parish-pump politics of Boston, it adds little to epidemiology Numerical data for the period are scanty, but such as there are are relegated to the appendix Little is said about diseases other than smallpox and yellow fever The " camp fevers " were presumably typhus, typhoid, relapsing fever, and dysentery The " sore throat distemper " in 1735 may have been diphtheria, if so, it came earlier than any recognisable epidemic in England. There must be more information than we are given about tuberculosis and syphilis All the diseases mentioned were importations from Europe Malaria appears once in the index but the reference is to ague, and in the 17th century this might be any acute fever Indeed the author seems unfamiliar with the European background in the early years A fatalist attitude to epidemic sickness may have been characteristic of the New England puritans but was equally apparent in Rome or Oxford

Diagnostic Radio-Isotopes

CHARLES A OWEN, Jr, M D, PH D, SC.D, associate professor of clinical pathology, Mayo Foundation Graduate School, Rochester, Minnesota Oxford Blackwell Scientific Publications. 1960 Pp 425 126*s*

THIS is an excellent book—authoritative, lucid, and concise. It begins with chapters on counters and counting, which could hardly be bettered, and are extremely well illustrated There follows a timely warning on radiation protection, short and to the point The real substance of the book, however, lies in the chapters on metabolism, hæmatology, and the investigation of the gastrointestinal tract and cardiovascular system each is a model of its kind, and is followed by an exhaustive bibliography (there are 528 references to iodine and the thyroid gland alone). No-one could read the book without profit and pleasure

It is unfortunate that so useful work should come to the British market so late, for the bibliography does not extend beyond 1956 This makes some sections—for instance, that on labelled insulin—notably incomplete Unimportant in itself, it is noticeable in a book remarkable otherwise for its thoroughness It is beautifully produced, well up to the publishers' high standards, and must be assured of many readers among those primarily interested in radioactive isotopes

Detoxication Mechanism

2nd ed R TECWYN WILLIAMS, PH D, D SC, professor of biochemistry, St Mary's Hospital Medical School London Chapman & Hall 1959 Pp 796 126*s*

THIS book has increased greatly in wisdom and stature since the first edition, which amounted to only 288 pages, and the author of this mature work is to be congratulated on the way he has brought up his child Students of the first edition need have no hesitation about acquiring the second, though they may regret the spectacular increase in price

Others less familiar with the importance of this rapidly expanding corner of medicine should know that the author has compiled a well-documented study of the way in which many of the well-known drugs are handled by the body after administration not only drugs, but all the hundred-and-one compounds that are now so apt to get into the body from pesticides, food additives, cleaning agents, and so on The historical touches here and there and the references to early discoveries are a pleasant addition to the text Apart from their interest and value, they show too how much the reader is beholden to the industry and balanced judgment of the author The book is an essential for the chemical pathologist, and a study of many of these reactions is likely to become an integral part of his training, if not that of all medical students in the years to come

Diagnosis of Congenital Heart Disease (2nd ed Chicago Year Book Publishers London Interscience Publishers 1959 Pp 866 203*s*)—The new edition of this outstanding book, first published in 1955, is larger by approximately 200 pages but follows closely the pattern of its predecessor The authors (Sven R Kjellberg, Edgar Mannheimer, Ulf Rudhe, and Bengt Jonsson), who form the cardiological team in the pædiatric clinic at Karolinska Sjukhuset in Stockholm, have now investigated in detail 742 cases of congenital heart-disease—nearly double the number seen at the time of the first edition—and they have thus been able to revise some of the earlier descriptions in the light of further experience Four new chapters have been added dealing with uncommon malformations not included in the previous edition, or in some cases incorrectly diagnosed at the original examination, and the sections on atrial septal defect and anomalous pulmonary venous drainage have been carefully revised All aspects of each malformation are clearly presented, but once again it is the angiocardiograms that catch the eye, and demonstrate how much information can be gained by selective angiocardiography Their excellence may perhaps be equalled but is unlikely to be surpassed

THE LANCET

LONDON 26 MARCH 1960

Immunisation Against Helminths

It is easy for anyone in this country to become smug about helminths, and to assume that nothing but improved sanitation is needed to eradicate them (except, of course, threadworms, which are at least as common in doctors' families as elsewhere) Of the three general methods of dealing with infestations—drugs, hygiene, and immunisation—drugs are often ineffective or, if effective, not curative, since a worm in the tissues can be almost as much trouble dead as alive The complex life-cycles of the helminths make them exceptionally vulnerable to preventive measures If waterworks, water-closets, mosquito control, and food inspection were universal they would render mankind invulnerable to nearly all the clinically important worms, but over much of the world these are still visions of the future, and in many places helminth infestation of one kind or another is a major factor in the economic backwardness that hinders sanitation Meanwhile, immunisation, the method hitherto thought impracticable, has been shown to deserve fresh thought and trial

Unquestionably, helminths can excite immune reactions In some infestations (trichinosis, for instance) one attack protects to a large extent against reinfection, while in others familiar reactions such as the Casoni test for echinococcosis and various sensitisation phenomena afford less direct evidence The trouble in harnessing such immune reactions is apparently twofold In many infestations the adult worms, lying free in body cavities or encysted, seem to be inaccessible to antibodies, and in others, such as filaria and schistosome, they seem to be untouched though not encysted Furthermore, no dead vaccine or extract so far devised has produced adequate immunity apparently only a live worm in the body is fully active immunologically Until recently this appeared to be an insuperable obstacle, but in the past few years it has been partly overcome by investigators whose work may prove to have wide applications

Husk of cattle is a disease of considerable economic importance in this and other countries It is due to the nematode *Dictyocaulus viviparus* The adults live in the bronchi the eggs are coughed up and swallowed and hatch into larvæ before being passed in the fæces Larvæ are eaten with the grass by a new host, penetrate the intestine, and migrate to the mesenteric lymph-nodes and thence by the blood-stream to the lungs, where they mature into adults The lungs may contain thousands of worms, and in calves the disease is often severe and may be fatal Intensive farming methods, by increasing the number of cattle per acre, increase the liability to the disease Survivors are immune from further attacks, and a group of workers at the Glasgow Veterinary School[1] found that experimental infection likewise protected against reinfection They showed also that a significant—though in practice useless—degree of immunity could be produced by injecting large amounts of homogenised dead worms with adjuvants, and that passive immunity could be produced by injecting the serum of immune animals The key advance, however, was their recognition that irradiated larvæ might invade the tissues and live there long enough to set up an immune reaction, but die before they could reach the lungs and cause disease The right doses of larvæ and of irradiation were not easily achieved With doses below about 20,000r the larvæ survived to produce disease with doses above 50,000r, the larvæ died too soon to cause immunity But a single oral dose of 1000 larvæ irradiated with 40,000r, given to calves later exposed to infection either artificially or by grazing on heavily infected pastures, produced roughly tenfold reduction in morbidity and mortality,[2] and two such doses, at a month's interval, gave complete immunity[3] Problems of producing the vaccine on a large scale have been overcome, and the commercial success of the method has been assured by field trials

If this were all, it could be readily argued that the method might not be generally applicable The worm concerned has a relatively long period of larval migration, during which an immune reaction has plenty of time to develop But the same Glasgow group has now shown that two further nematodes can be tackled in much the same way—*Hæmonchus contortus*, the stomach worm of sheep,[4] and *Uncinaria stenocephalus*,[5] a hookworm of the dog This finding, by widening the range of species, both of host and parasite, increases the probability that the method is generally applicable But it also destroys the argument that extensive migration in the tissues is essential The dog hookworm can infect through the skin like the human hookworm, but it is more usually ingested and then reaches the gut directly without any migratory stage both vaccine and challenge dose were given orally in these experiments As for hæmonchus, standard accounts suggest that no more penetration is achieved at any stage than is necessary for its attachment to the sheep's stomach, though there is now some evidence that there may be some penetration of the mucosa by larvæ

By this ingenious method of using irradiated larvæ it might prove possible to prevent natural infection in man by blocking the original penetration or attachment of the larvæ Such immunisation, by reducing the number of carriers as well as by promoting the general health of the community, could be at least a valuable adjunct to the hygienic attack on any worm infestation Extension of the method to man presents special difficulties often he will be himself the only source of parasites, and the only test object, and the organisation of safe clinical trials may be a most anxious matter But the rewards could be great Which species will prove susceptible, and which resistant, only experiment can tell Judging by the results with uncinaria it might be well to make a start on hookworms

Cæsarean Section and Hyaline Membrane

Hyaline membrane is, it seems, especially liable to form in the lungs of infants born by cæsarean section[1–3] Latham et al[4] made a pathological study of the lungs of 407 infants weighing over 1000 g Hyaline membrane was found in 124 (31%), of whom 36 (79%) had been delivered by cæsarean section Soiva[5] reported that in infants delivered by cæsarean section respiratory difficulty with cyanosis sometimes appeared in the first few hours of life, and in such cases hyaline membrane was found at necropsy McNeill[6] believed that there was an inherent perinatal loss of the order of 1% in infants delivered abdominally these deaths were attributable to hyaline-membrane disease and to atelectasis Hyaline membrane has also been found with some frequency in the lungs of infants whose mothers had diabetes mellitus[2 4 7] Winter and Gellis[7] found hyaline membrane in the lungs of 60% of infants who died in the neonatal period and whose mothers had diabetes, and both these workers and Nesbitt and Anderson[8] emphasised that many of these infants had been delivered by cæsarean section Cardell[9] examined the lungs of 12 infants of diabetic mothers delivered by cæsarean section Only 1 weighed under 2500 g at birth, and all had a period of gestation between 34 and 36 weeks 11 showed hyaline-membrane formation

Snyder[10 11] suggests that infants delivered by cæsarean section at term aspirate the fluid which surrounds them before delivery, and that this fluid is concerned in the subsequent development of a hyaline membrane Maternal complications such as accidental hæmorrhage or placenta prævia may lead to contamination of the liquor amnii with blood, and, if the membranes have been ruptured for some time before delivery, bacterial contamination is a further possible hazard Snyder[12] regards blood and debris found in the air passages and lungs at necropsy as evidence of intra-uterine respiration A similar chain of events was demonstrated experimentally in the rabbit[13 14] Snyder[10] has investigated the cases of 56 infants delivered by cæsarean section at term All weighed over 2500 g, 12 were stillborn and 44 liveborn but died within three days In over 90% necropsy yielded evidence of respiration before delivery, characterised by the presence of blood, epithelial cells, and debris in the air passages 15 infants were delivered by section before the onset of labour, and in each of them blood was found in the bronchi and alveoli, in 14 of the 15 a hyaline membrane was also present Of the remaining 41 infants 29 were liveborn and 12 stillborn Section had been carried out during labour in these cases Of the 29 liveborn infants 28 had blood in the lungs (in considerable quantity in 18 cases), epithelial cells, cornified cells, and debris were found in the lungs of all the infants, in 13 of the 29 a hyaline membrane was found None of the 12 stillborn fœtuses showed any evidence of maceration Histological examination of the lungs revealed blood in the air passages, and this was pronounced in 5 cases, epithelial cells and debris were found in all cases, but *no* membrane was seen in the lungs of any of the 12 Thus the incidence of hyaline membrane was much higher in the groups of infants delivered before the onset of labour Snyder is inclined to believe that complications during labour may depress fœtal respiration

In a further investigation Snyder[11] studied 22 premature infants delivered by elective cæsarean section before the onset of labour All were under 2500 g at birth but 17 weighed between 2000 and 2450 g Maternal diabetes was the indication for section in 4 cases On histological examination of the lungs blood was found in the bronchi and alveoli in every case, epithelial cells and cornified cells were also present In 11 of the 22 infants large masses of erythrocytes mixed with debris and cellular material were seen in many bronchi and alveoli A hyaline membrane was situated round the walls of alveoli and bronchioles in the lungs of *all* infants in this series In some areas this hyaline material was homogeneous, and in others it was mixed with erythrocytes and cellular debris The membrane was thought to have caused obstruction to air entry, since many large portions of lung were incompletely expanded or were collapsed

Both of these two investigations revealed a high incidence of membrane formation in infants delivered by elective cæsarean section in 14 of the 15 full-term babies and all the premature babies membrane was found on histological examination (whereas membrane was present in only 13 of the 29 infants delivered by section after the onset of labour) Snyder suggests that this is the result of obstruction of the air passages with blood, and that contamination of the liquor amnii at the time of incision of the uterus is the main factor in membrane formation There is, of course, no proof that all the blood in these infants' lungs was of maternal origin. Snyder's contention that complications of labour and asphyxia are likely to damp down fœtal respiratory movements is more debatable It is generally accepted that a considerable amount of amniotic-sac content is likely to be aspirated if the fœtus becomes anoxic before delivery, but such aspiration is now regarded as a less likely cause of hyaline membrane than transudation from the pulmonary vascular bed[15] Laufe and Stevenson[16] suggested that both mechanisms might operate, and that material aspirated into the infant's lung might potentiate the clotting of plasma-protein which had escaped from the pulmonary vessels This view is supported by the findings of Craig et al[17] These workers are convinced that the chief constituent of hyaline membrane is fibrin When portions of lung from affected infants were injected with plasmin and then incubated, the membrane was partly dissolved and squames and

other debris were found in the portion of membrane which was still visible. This seems to suggest that debris from the liquor amnii may possibly act as a scaffolding on top of which fibrin and other structureless material is laid. So far the action of plasmin has been observed only in vitro. Whether it could be applied therapeutically to destroying the membrane in the live infant is unknown.

Not all agree that the incidence of hyaline membrane is higher in infants born by cæsarean section than by vaginal delivery. STRANG et al [18] reviewed their results of cæsarean section over a period of ten years and concluded that the risk of membrane for mature babies in elective cæsarean section was small, and their results for 36 premature infants did not differ from those for all premature babies in their hospital. The suggestion that hyaline membrane is more commonly found in the infants of diabetic mothers has likewise been denied. CLAYTON [19] reported, in 201 diabetic pregnancies, hyaline membrane formation in 11% of infants delivered vaginally and in 13% delivered by cæsarean section. He concluded that the membrane formation was not clearly related to the method of delivery. Most of the neonatal deaths in his series occurred among infants delivered by section, but only because this was the commonest method used. BRUDENELL [20] also believes that the neonatal death-rate among offspring of diabetic mothers is about the same whether delivery is per vaginam or by section.

These conflicts of opinion are not easily resolved. The trouble lies partly in the difficulty of collecting a large series in any one unit and partly in the uncertainties of assessing high-risk groups from retrospective analysis of pathological material. Thus it is not known how many uneventful cæsarean sections were carried out before the total number of fatal cases reported by SNYDER were collected. At present careful clinical studies apparently indicate that there is little or no inherent risk to the infant from elective cæsarean section at or near term. Pathological investigations, on the other hand, seem to indicate that a disproportionately large number of infants with a birthweight of over 2500 g who have died of pulmonary hyaline membrane have been delivered by cæsarean section. Some of these no doubt are infants of diabetic mothers and are not, strictly speaking, mature. The differences of opinion are probably more apparent than real.

Overriding the Parents

IMPORTANT issues of public policy are raised by the Sheffield Regional Hospital Board's new arrangements for cases where a parent refuses consent to treatment thought necessary to save his child's life. The essence of these arrangements is that an order—quickly obtained from a magistrates' court under the Children and Young Persons Act—shall place the child in the care of the local authority's children's officer, who will then give the necessary consent.

The parent's reason for withholding consent is usually that he has a conscientious objection to the proposed course of treatment. In particular, certain sects have convictions on blood-transfusion which they are prepared to uphold at all costs, and some publicity has been given to these convictions by a case in which a child died [1] and also by a television programme about an imaginary hospital. However wrongheaded such opinions appear to the great majority, we must recognise that they are deeply and sincerely held—so much so that the parents may be willing to risk the loss of the child and to face a charge of manslaughter. Most people will think it right that opinions of this kind should be overridden when there is clear risk to a child's life or health, but such a decision is not one that the community should regard lightly. It should be taken, if at all, by a judicial body. Such a body, to be effective, would sometimes have to act swiftly, and, as a means of getting a quick and reasonable decision, probably the most suitable tribunal is, as the Sheffield board believe, the local magistrates sitting as a juvenile court. Magistrates can readily be convened and have generally displayed the qualities of tact and common sense needed for comparable tasks.

Nevertheless, the Sheffield proposals are open to criticism. The Children and Young Persons Act has never, apparently, been used in the way proposed by the board, and there is some doubt whether it could lawfully be used thus. The jurisdiction under the Act depends on the child being "in need of care and protection." A child in need of care and protection is defined as one who "having a parent or guardian ... not exercising proper care or guardianship, is neglected in a manner likely to cause him unnecessary suffering or injury to health." In describing the proposed procedure as "merely a streamlining matter",[2] the board's solicitor apparently assumed that the legal process was available. But the Act was obviously intended for quite different circumstances, and, even if it could in fact be stretched to cover cases where the parent's "neglect" is refusal of permission for particular medical or surgical treatment, this extension would surely be much less satisfactory than new legislation designed for the new purpose. In such legislation the circumstances in which the magistrates take action could be carefully defined, and there would be no need for the fiction by which the child is placed in the care of the children's officer.

The hospital board also seem to have ignored the maxim that justice must not only be done but also be seen to be done. In this kind of case it is especially important that the aggrieved parent should feel sure that his objections have been fairly dealt with by an independent tribunal. The board's arrangements could have been described in happier terms:

> "Discussions have taken place with certain of the responsible local authority and magistracy interests and a procedure has been defined where on receipt of a telephone call from a hospital concerned the children's officer would attend at the hospital on behalf of the local authority and the justices' clerk would arrange for a juvenile court to be set up at the hospital itself within the shortest possible time."

No doubt there would often be advantages in holding the court at the hospital itself, but it is for the members of the court to decide where they will sit To give an impression that the magistrates are at the beck and call of the hospital authorities would certainly be a mistake

Annotations

PENICILLIN HYPERSENSITIVITY

REACTIONS to penicillin[1–5] have increased in recent years, and today most severe hypersensitivity reactions and deaths are caused by this drug[6] The increase is not surprising in view of the enormous quantity of penicillin prescribed, particularly as penicillin can cause sensitisation and provoke reactions in almost any dosage and by any route of administration Penicillin is best avoided entirely in treating a patient who has previously had even a mild reaction, although some physicians[7] consider that if the indication for penicillin therapy is sufficiently strong—for example, in cases of syphilis or subacute bacterial endocarditis—it should be used with anti-histamines or steroids to control any sensitivity reactions A report by Siegel[8] clearly shows that a sensitised person, even if not given penicillin therapeutically, may still encounter it in other ways and develop serious reactions

Cow's milk nowadays may contain penicillin because milk from cows with mastitis treated with the antibiotic is often included in bulked milk supplies In the United States 6% of milk samples and in different parts of England and Wales[9] from 5 to 47% of samples have been shown to contain penicillin, the range of penicillin concentrations in the samples was similar in the two countries Siegel determined the oral dose of penicillin which would cause reactions in sensitised people by using their sera to produce passive sensitisation in areas of skin of normal subjects who were then given penicillin by mouth, the direct experiment of feeding penicillin to those known to be sensitised carried too great a risk of severe reactions He found that there was enough penicillin in a glass of any of the penicillin-contaminated milks of the American survey to cause clinical reactions This experimental evidence is supported by reports of severe dermatitis provoked by penicillin in milk[9] and of anaphylactic shock from drinking a single glass of milk[8]

An anaphylactic reaction following an injection of testosterone in a woman known to be sensitive to penicillin led Siegel to investigate the possible contamination with penicillin of syringes previously used to inject the antibiotic this patient was found to be very sensitive to penicillin and not at all to testosterone All-glass syringes contaminated with penicillin were rinsed three times and boiled for fifteen minutes with the plungers in place Penicillin was still detectable by skin tests after this procedure When the barrel and plunger were separated before boiling, penicillin was not detected Further, as the antigenic activity of penicillin, though reduced, was not destroyed after sixteen hours' boiling, the water in a steriliser in which syringes are boiled may contaminate clean syringes with penicillin

A third way in which a sensitised person may accidentally encounter penicillin is by inhaling it in the air, and Siegel mentions two nurses who were unable to work in hospital wards for this reason (Gould[10] in this country has directly demonstrated the presence of penicillin particles in the air of a hospital)

Finally Siegel states that the amount of penicillin in Salk poliomyelitis vaccine is sufficient to cause reactions in highly sensitised people This accords with several reports of reactions to Salk vaccine

These hidden contacts with penicillin explain some otherwise obscure hypersensitivity reactions, and, by suggesting ways in which people who have never been treated with the antibiotic can yet be sensitised to it, they throw more light on those puzzling cases of anaphylaxis following a first injection of penicillin

There remains the practical problem of how to detect penicillin hypersensitivity in patients requiring the drug Undoubtedly a history of a previous reaction—however slight—is of most value Direct skin tests[3] have a place, but these have the disadvantages, on the one hand, that they may be negative in some sensitised people and, on the other, that the patient may be so sensitive that as little as 0 000003 unit of penicillin intradermally causes a constitutional reaction[8] Testing an area of a normal person's skin after passively sensitising it with serum from the patient is safe but too cumbersome except for research purposes Laboratory tests for the penicillin antibody[11 12] which agglutinates penicillin-treated red blood-cells is of no assistance, because the presence of this antibody merely indicates previous contact with penicillin and not necessarily sensitisation to it A carefully taken history and an ampoule of adrenaline always within reach seem to provide a rational approach to this possible complication

RETINITIS PIGMENTOSA AND CONGENITAL DEAFNESS

RETINITIS pigmentosa is the classical example of a condition, at first sight unitary, which may be caused by several different mutant genes Some affected families show the pattern given by an autosomal recessive, others that given by a dominant, and still others that given by a sex-linked recessive gene[13] In addition, there are distinct mutant genes which cause retinitis pigmentosa in association with other abnormalities Just over a hundred years ago, von Graefe[14] reported the association of retinitis pigmentosa and congenital deafness in 3 of a family of 5 *Julia Bell,*[15] *in 1933 collected 93 recorded* instances of this association In 1945 Lindenov[16] confirmed that the syndrome was almost certainly due to an autosomal recessive, and showed that it was responsible for about 6% of cases of congenital deafness in Copenhagen and the adjoining counties, hence it may be inferred that the prevalence of the condition there was of the order of 3 per 100,000 Hallgren[17] has made a new study of the syndrome in Sweden, attempting to ascertain all the cases in the country The admirable Swedish system of medical and social support for the deaf of all ages enabled him to identify 151 living patients—which probably represents the majority in the country over the age of 10, and a high proportion of those younger than this The prevalence over the whole country was 2 4 per 100,000,

which is close to Lindenov's figures for Denmark. The disorder is commoner in the more sparsely populated northern counties of Sweden than in the south. In the three most northern counties, the prevalence was found to be over 1 in 10,000, whereas in Stockholm there were only 3 cases in a population of over half a million.

Besides the two main features of the syndrome, vestibular ataxia, cataract, mental defect, and psychosis may be found. Cataract, which develops in the majority of patients over the age of 40, may be regarded as another manifestation of the gene. The majority of patients show ataxia in the form of a swinging gait; the degree of this ataxia is related to the degree of hearing loss, and Hallgren showed that it is probably due to loss of labyrinthine function. The question whether true mental deficiency is associated with the syndrome is not easily answered, because of the handicap of congenital deafness. Hallgren tried to overcome this difficulty by comparing the abilities of his patients with those of patients with congenital deafness of other types. He considered that over 20% were, to some degree, mentally retarded, but that only 2–3% were imbeciles or idiots. This does, however, suggest a real genetic association with mental deficiency. The incidence of psychosis—mainly schizophrenic-like illnesses—in the patients was also over 20%. This may reasonably be attributed to the stress of congenital deafness and the inexorably progressive loss of vision in early adult life.

Hallgren has also made a genetic analysis, which is especially valuable since it is based on much the largest consecutive series of patients. He confirms that a recessive mutant gene is the cause. The proportion affected among the sibs of propositi is close to 1 in 4; about a third of the propositi are the products of consanguineous marriages, and a sixth the product of first-cousin marriages. The frequency of the heterozygous carriers of the gene is estimated to be between 1 in 200 and 1 in 100. Genealogical investigation showed that there were ancestral connections between 30 of the 102 families. One large pedigree contained no less than 12 affected sibships.

The control of recessively determined disorders of this kind depends essentially on detection of the heterozygous carrier. Hallgren found no clinical manifestations of the gene in heterozygotes, and detection of these carriers may have to wait until the exact nature of the underlying gene-determined chemical abnormality is discovered.

IN AND BY THE COMMUNITY

THE new Mental Health Act relies largely on the expansion of community care for the mental patient. To be effective this care must be offered not only in the community but by the community. People must accept the indirect responsibility, through the agency of local authorities, of helping to develop mental-health services, and the direct, if non-statutory, responsibility of helping patients who rejoin the community as their neighbours. The Mental Health Act has become law; that it will not become practice unless people recognise that "mental health is everybody's business" is the theme of Miss Nesta Roberts' survey[1] of the Act and the community. She clears up some popular misconceptions—"patients will not surge out of the hospitals in a mighty tide, which is just as well, since hostels in which they might live cannot be conjured up immediately". She suggests how existing services may be sensibly expanded—"to take over a large, remote and probably rather damp house and staff it with a gardener-handyman and a cook-general is not to establish the kind of home that is needed". But expansion in bricks and mortar, she recognises, must wait on staff training which is even more urgent. The interval she believes can usefully be filled by intelligent propaganda among the public, and her own booklet is a brilliant start to the exercise.

LATEX AGGLUTINATION REACTION IN NON-RHEUMATIC DISEASES

WHEN certain apparently inert particles such as latex (polystyrene) are treated with human γ-globulins they become agglutinable by the sera of most patients with rheumatoid arthritis.[1] The test is approximately equal in sensitivity to the Rose-Waaler differential agglutination test (D.A.T.) but is much simpler to perform. It has gradually become apparent, however, that it lacks the specificity of the D.A.T., being positive in a wide variety of unrelated non-rheumatoid conditions.[2] A systematic study of these so-called false-positive tests has been undertaken by Dresner et al.[3 4] with most interesting results.

The sensitivity of the latex test, like that of the original D.A.T., can be greatly increased by the modification introduced by Ziff et al.[5] which detects the ability of a serum or its euglobulin fraction to inhibit a positive agglutination. Normal sera contain such an inhibitor, which is absent or much reduced in rheumatoid sera even when the agglutinating factor is itself too weak to be detected by the usual D.A.T. or latex tests. By such a latex inhibition test in place of the standard latex agglutination test, Dresner et al. increased the proportion of positive results in a series of 137 rheumatoid arthritics from 62% to 96%. Of a control group of 140 apparently healthy subjects only 7 gave positive results; all 7 had an upper respiratory viral infection. When, however, a series of patients with non-rheumatoid diseases were studied a high proportion of positive inhibition tests was found in three groups—namely, hepatocellular disease, viral infections, and syphilis. Of 96 patients with hepatocellular disease (which included portal and biliary cirrhosis as well as viral hepatitis and hepatic metastases) 68 gave a positive inhibition reaction. Furthermore, of 19 positive reactions in patients with biliary cirrhosis, 10 reverted to normal during a clinical remission. Of the 35 cases of virus infection 29 were positive. Apparently no single virus is responsible: at least eight different viruses were associated with the various illnesses in this group. The syphilitic group consisted of 19 serologically positive patients, of whom 18 gave a positive latex inhibition test, and 3 serologically negative, all of whom also gave a negative latex test. Of the remainder of the disease controls—i.e., those with non-rheumatoid diseases—only 7 out of 219 were positive.

These results indicate that the latex inhibition test is a distinct advance on the standard agglutination test since a positive result is obtained in almost every patient with rheumatoid arthritis. Previous modifications of these

serological tests for the rheumatoid factor have almost invariably been associated with a corresponding loss in specificity, and the present modification is no exception But inclusion by Dresner et al of a wide range of controls has shown that this loss in specificity does not greatly impair the value of the test, since the vast majority of the false-positive results belong to three distinct groups of diseases which should only rarely lead to confusion with rheumatoid arthritis Moreover, the positive results in these non-rheumatoid states may themselves prove of considerable diagnostic value

Dresner's findings emphasise once again the fundamental difference between the factors responsible for latex agglutination and the agglutination of red blood-cells sensitised with amboceptor Whereas in hepatic disease, viral infections, and syphilis the latex inhibition test is commonly positive, the D A T is almost invariably negative It seems that the true rheumatoid factor has a wider range of specificity with regard to the modified γ-globulins with which it can react than the agglutinating factors found in other diseases

GENETICS OF SCHIZOPHRENIA

NO-ONE can seriously doubt the importance of genetic factors in schizophrenia, but their mode of action is still undecided Twin studies have shown that the concordance-rate for monozygous twins is much greater (76–86%) than in dizygous twins (14%),[1, 2] and this is clear evidence that heredity [3] plays a part Kallman [2] has found that the consanguinity-rate among parents of schizophrenics (5 7%) is much higher than in the general population (others have found much smaller increases [4, 5]), and this might seem to be good evidence for Kallman's hypothesis that schizophrenia is inherited through a recessive autosomal gene Closer examination does not justify this assumption [6] Using Dahlberg's formula to calculate gene frequency of schizophrenia in the general population, it is necessary to suppose that there are some 125 distinct autosomal genes That this is extremely unlikely is shown by the high rate of schizophrenia in the children of two schizophrenic parents (who would not be likely to have the same genes if schizophrenia were due to 125 different ones) Furthermore the fact that the rate of schizophrenia is no lower or is slightly higher in the children (16 4%) than in the siblings (14 3%) points strongly to transmission by a dominant gene Book,[4] in his study of an isolated North Swedish community, postulates a dominant gene of incomplete penetrance, but this is a very unusual group, and Book's results may not be applicable to schizophrenia elsewhere A dominant gene explains many of the findings, but not all unless additional assumptions are made Slater [7] has suggested that transmission may be by a gene intermediate between dominant and recessive

Hallgren and Sjogren,[8] in an exhaustive genetico-statistical population study of a type that the Swedish have made peculiarly their own, have found an association between schizophrenia and mental deficiency There were significantly more mental defectives among schizophrenic propositi but not among siblings, and there was no increase of schizophrenia in the siblings of defective propositi Hallgren and Sjogren conclude that an explanation cannot be found on the basis of their material, but that this does not support the assumption that abnormalities classified as mental deficiency are manifestations of early schizophrenic deterioration An association between schizophrenia and mental deficiency has also been found by Book [4] (although the results were not statistically significant) and by Slater [9] who, in a study of maternal uncle-nephew relationships, tentatively suggested that a sex-linked recessive gene might be responsible

Rosenthal,[10] by an ingenious analysis of Slater's twin series, has investigated the possibility that, while some cases are genetically determined, others are not He compares the monozygous twins concordant for schizophrenia with those discordant, reasoning that, if some schizophrenia is genetically determined and some not, the former should be found predominantly in the concordant twins and the latter in the discordant That schizophrenia is almost totally absent in the families of the discordant pairs and present in about 60% of the families of the concordant seems to support the hypothesis The male affected discordant twins (females were less predictable) tended to have a better premorbid adjustment than the concordant twins (though adjustment was poor in both groups), and the illness was more often paranoid, whereas in the concordants it was commonly catatonic Environmental factors, then, seem to be more important in the ætiology of the paranoid form of schizophrenia

The basis of schizophrenia remains undecided, but it seems likely to be heterogeneous in some cases (probably among the paranoids) environmental factors are of much importance, but in most, genetic factors predominate Even if heredity plays a great part in schizophrenia, this does not necessarily mean that the cause is some inherited anomaly (Kety [11] has pointed out that in tuberculosis, judged by contingency and twin studies, constitution is only slightly less important than in schizophrenia), but such a defect does seem probable

SNAKEBITE IN U S A

WITH less than 1000 bites a year and a fatality-rate under 2%, snakebite is not a serious medical problem in the U S A Rattlesnakes are the only important cause of envenomation They belong to the family of crotalidæ or pit vipers (the pit, between the eye and nostril, is a thermosensitive organ for self-protection and for detecting prey), examples of which are found in America, India, and elsewhere in Asia Rattlesnakes, so-called because of their unique tail adaptation which rattles when the snake is disturbed, are confined to the American continent In a review of bites in south California Russell [12] mentions the importance of early administration of antivenene (but not the fact that this is largely beyond the doctor's control) and advocates injection by local, intramuscular, and intravenous routes He does not recommend antihistamines and steroids except for serum reactions Although blood-transfusions were given to 5 out of 15 patients, their value is not assessed Reid [13] has claimed that in severe envenomation following Asian viper-bites adequate blood-transfusion is the most important therapeutic agent

Medical Education

PRECLINICAL BIOCHEMISTRY

A View from London Bridge

ARNOLD H SCHEIN*
B S , Ph D
ASSOCIATE PROFESSOR OF BIOCHEMISTRY,
UNIVERSITY OF VERMONT COLLEGE OF MEDICINE,
BURLINGTON, VERMONT, U S A †

THE unrest and ferment in all phases of medical education in the United States are impressive Much of the pressure for change stems from broad agreement that now, more than ever, lines of demarcation between erstwhile preclinical disciplines are fading The belief is widely held that old teaching practices cannot cope with the explosion in scientific and medical knowledge Care, money, and valuable time are lavished upon educational programmes designed to improve teaching and learning It is de rigueur for medical schools of any reputation to have at least one teaching " experiment " under way After more than a decade of vigorous experimentation, proof is lacking that returns are even remotely proportional to investment, real achievement is hampered by lack of adequate controls and objective criteria for judging the success of altered curricula and teaching methods Yet it is recognised that grave problems exist, and an attempt is being made to solve them Nothing ventured, nothing gained

My principal aims in going to London were to assess the role of biochemistry and to see something of British developments in medical education Discussions with heads of departments, and other teachers, at each of the ten London medical schools offering the 2nd M B , as well as my own teaching experiences, observations, and impressions gathered over an academic year, provide the basis for this article

Pedagogically attractive aspects of London medical education (and of biochemistry) which could be profitably emulated in the United States—including a superior scale for grading students, excellent intradepartmental correlation, the external examiner system, chemical pathology, and the relaxed mien of the students—will be elaborated upon in a separate article designed for American colleagues Here I shall concentrate rather upon those aspects of London medical biochemistry which in my opinion could be significantly improved Many of my statements and inferences will be considered too sweeping, or inconsistent with the experiences of other interested observers, particularly those with a domestic frame of reference. If so, they must gather whatever wheat they may find among the chaff My suggestions are not original, and many of them have been made at one time or another by London colleagues Nor have I any wish to suggest that London weaknesses are unique Similar deficiencies, particularly in the realm of staff, interdepartmental correlation, and laboratory teaching prevail in the United States to a marked degree.

BIOCHEMISTRY AND ANATOMY

A strong case can be made for reasonable emphasis on biochemistry in light of the contributions of this science to current advances in medicine In the United States, biochemistry was many years ago advanced to essentially equal status with gross anatomy In London, however, anatomy is by far the major subject of the preclinical curriculum and biochemistry is a minor subject

The following paraphrased comments from British colleagues aptly describe the situation

" The trouble is not with the British students, but with the archaic system of giving priority to anatomy in our teaching Whatever the time-table says, a great majority of our students apportion their time as follows counting total for a week=10, anatomy=7, physiology=2, biochemistry=1 Some may use 6 3 1, or a few even 5 4 1, but it is a tragic fact that biochemistry remains about 1

" There are several reasons for this (a) A tradition which goes back to the time when anatomy was the only preclinical subject (b) The fear of dire consequences inculcated in the hearts of all medical students if anatomy is not mastered Too often the implication is that anatomy is the *only* important subject of the curriculum and the rest is best forgotten (c) The fact that the great emphasis on anatomy is upheld by the college and university administration and by nearly all the clinical teachers (d) The fortnightly anatomy vivas There is no counterpart of these vivas in biochemistry or physiology

" As a result of all this the young students are completely duped into really believing that anatomy is of vast and major importance, and far more so than the rest of their studies The whole system is woeful, tragic, and about forty years out of date "

I can bear out these observations

Thus, the outstanding difference between London and United States medical biochemistry is that in the former biochemistry—despite adequate hours, course content, and competent staffs—is not taken seriously by the students as a valuable foundation for medicine The chief reason for their indifference is the overwhelming emphasis upon anatomy, which dominates their thoughts, interests, and study time As a consequence, parallel studies are neglected to a greater or lesser degree There is a distinct reluctance to commit valuable and necessarily limited brain-space to biochemistry at the expense of anatomy The student lives from one anatomy viva to the next A talented note-taker, he does not *listen* to lectures or read biochemistry Students comprehend little of the subject matter or significance of lectures and practical work at the time of presentation Lecture notes may be revised and studied *just before* trial examinations The London student's capacity for cramming is impressive.

The concepts of biochemistry, to a large extent, rest one upon the other If crammed, these concepts cannot be assimilated and then integrated to form a framework for that aspect of human biology known as medicine Failure to grasp biochemical principles results in failure to apply them adequately in the recognition and treatment of disease

A single, but perhaps representative, opposing view of a senior London anatomist is summarised

1 Anatomists are all medically qualified and therefore better able to determine the needs of medical students It is true that sound anatomical training is by far the most useful of all studies for general practitioners

2 Proper dissection of the whole body and thorough knowledge of structure is time-consuming and demanding Any compromise of this fact will erode the foundations of medical education. Also existing regulations require the dissection of the whole human body (The last statement is no longer true)

3 Students use anatomy as an excuse for not doing well in other subjects, and other disciplines make anatomy the scapegoat for their own inadequacies

4 Teaching anatomists are unaware of demands by clinicians for more emphasis on biochemistry in the curriculum, indeed it has been the other way around—with the demand for more thorough training in anatomy

---

[*] Exchange senior lecturer, 1956-57 department of biochemistry, The Medical College of St. Bartholomew's Hospital, London

[†] Aided by a grant from the National Science Foundation

5 Medical students now receive satisfactory anatomy training—not too much, not too little Anatomy has already been extensively shortened—no more cutting can be justified If it is true that students neglect their physiological sciences in favour of anatomy, it would be desirable to lengthen the preclinical interval and devote a few trimesters exclusively to the other preclinical subjects

Point 3 has more than a grain of truth Point 4, to my surprise, seemed to be substantiated by my own experiences and by contacts and conversations with clinicians, clinical teachers, and practitioners in London. This is in marked contrast to the plea by clinical acquaintances in the United States for greater emphasis on *physiological sciences* during preclinical *and* clinical years

I am not competent to discuss whether London students are "overeducated" in anatomy However, a teaching system which for almost two years suffers students' neglect of one, and perhaps two, of the fundamental basic sciences cannot be said to lay a proper foundation for the practice of modern medicine

The situation is completely recognised by nearly all the preclinical staff (other than anatomy), and pressures are being exerted to modify the curriculum A strong case for judicious pruning of anatomy in Great Britain has recently appeared [1] It is perhaps significant that the recent report of the General Medical Council, in its recommendations (which are deemed to have the force of regulations) on dissection of the human body, fails for the first time to include the word *whole* [2] In the past, strict and literal interpretation of this word has proved a stumbling-block to equal priority for physiology and biochemistry

Pedagogic devices such as tutorials, increasing the instructor's time with students, increasing instructor/student ratio, printed study questions, written assignments, and insistence on class attendance are futile if students will not make an effort to learn biochemistry The students are not to blame They simply respond understandably to more immediate and overt pressures

Significant improvement in London biochemistry may have to wait until anatomy is somewhat deflated and biochemistry is recognised by students and clinical staff as a major subject The London medical student has yet to be convinced that the understanding and application of biochemical principles is necessary for the practice of good medicine, and only clinicians who are so convinced can change his attitude This was the lesson learnt in the United States when a *similar* situation with regard to anatomy prevailed Clinicians, and not preclinical instructors, set the mode If the medically qualified clinical teachers respect and utilise the scientific aspects of medicine the message will reach even preclinical students

STUDENTS

It is admirable that almost all London students enjoy tuition and living grants, and that no worthy person who survives the rigorous British academic elimination contest is denied medical education on economic grounds Also creditable is the lack of a geographic basis for student selection In the United States, residence restrictions (many State-supported universities do not accept applicants from outside their own State) and the high cost of medical education are factors which tend to lower the quality of medical students London students are $2^1/_2$ to 4 years younger and less mature than their American counterparts However, British general educational background is superior, except in science

The London medical student outwardly exhibits a rather carefree, nonchalant attitude and a steadfast determination not to be overwhelmed by work—the result, it is claimed, of his intensive, somewhat monastic, premedical schooling The university offers release to academic and living freedom, and it is understandable that at first he takes advantage of this heady new environment In contrast to a large proportion of medical students in the United States, only a few London preclinical students are burdened with the blessings (?) of matrimony and parenthood

Because British secondary education lays stress on command of the written word, the London student's examination answers are, compared to those of his American counterpart, prose masterpieces One can hardly overstate this difference in skill of written communication In class discussion, however, the Londoner tends to be tongue-tied and shy He is terribly afraid of making an ass of himself or showing off It is evident that his inhibited performance is confined to the classroom, since informal social meetings, flavoured by suitable liquid refreshment, reveal him to possess a positive talent for oral expression He is likely to be fluent on all topics other than those connected with his studies

FACULTY

As in the United States, instructors are likely to regard teaching as a necessary chore, and occasionally as a nuisance This latter attitude, based on competition for research versus teaching time, and in London upon the general lack of student interest in biochemistry, is unfortunately shared in reverse by a large number of students The atmosphere is not conducive to development of teaching enthusiasm, and in such an environment learning rarely flourishes Some London biochemistry instructors, vitally concerned with education of medical students, make mighty efforts to breach the solid wall of student apathy, but these are essentially futile

With few exceptions members of the teaching staff avidly pursue their research interests Only senior members are bogged down with committees and administrative duties The primary task of the younger man is research, and new personnel are selected more for their research potential and productivity than for discernible aptitude or interest in teaching The same criteria to a large extent guide financial reward and promotion

Teaching versus research recognition is an endlessly debated subject in American universities In London as elsewhere an undercurrent of dissatisfaction with the system of rewards was evident The competition between teaching and research time is a real one, and, since the teaching of medical students demands scholarship of a high order, rewards and incentives should not be withheld from the man who is creative primarily in the classroom

In only half the schools visited did I find any demonstrable curiosity about the teaching of biochemistry in the United States Some teachers were frankly envious of the stimulating biochemistry teaching climate there, others felt it to be a terrible drag on research, and one, while decrying London biochemistry, felt (with some justification) that the emphasis on biochemistry in the United States might be as misplaced as the emphasis on anatomy in England At one school the entire staff gathered to interrogate the visitor, the experience was highly stimulating and mutually informative

---

2 General Medical Council Recommendations as to the Medical Curriculum, 1957

CONTENT OF BIOCHEMISTRY COURSE

A substantial number of lecture and practical hours at many schools were devoted to organic chemistry [3] Retention of this subject in the already swollen preclinical curriculum is an anachronism Organic chemistry should be transferred to the school or 1st M B period Some medical colleges have effected changes to this end, but not completely After the study of the chemistry of carbon compounds, the subject-matter of the biochemistry course is quite similar in London and in the United States [4] Some London departments omitted a topic or two, some blended topics (e g, metabolism and vitamins) and some, like many American departments, left acid-base, water balance, and endocrinology to physiology

In almost all London schools preclinical biochemistry is supplemented by formal consideration of "abnormal" biochemistry (chemical pathology) during clinical years Preclinical biochemistry is university-oriented rather than clinically oriented This is ideal in theory, clinical teachers may expand upon the previously established foundation of "normal" biochemistry The ideal is perhaps only remotely realised in practice, for, though it may seem wise to delay discussion of abnormal biochemistry until clinical material is at hand, the biochemistry foundation of the London medical student—quite noticeably shaky at any time—may have crumbled and vanished very soon after his 2nd M B The base upon which abnormal biochemistry should rest is likely to be non-existent

In the United States, some chemical pathology is incorporated into preclinical biochemistry Perhaps as a consequence, there seems to be little doubt in the students' mind of the importance of biochemistry in medicine In addition, the concepts of genetic, metabolic, and structural abnormality are developed as vistas broaden throughout the preclinical and clinical years This development is also a feature of London medical education

Teachers of biochemistry may well consider the advisability of widening the scope of their interests, reading, research, and teaching in the area of biochemical abnormality Without going overboard, this step would aid in motivating students and in bridging the very wide gap between preclinical and clinical studies To the same end, chemical pathologists may be invited to participate in the latter part of the biochemistry course Such a programme has already been instituted in at least one school, and has been found a desirable adjunct to the teaching of biochemistry

TEXTBOOKS

The London student relies mainly on lecture notes Only half of the departments urge students to buy a textbook The most popular are Thorpe's *Biochemistry for Medical Students* and Bell, Davidson, and Scarborough's *Textbook of Physiology and Biochemistry* There are no reading assignments nor do students make any effort to read subjects in advance of lectures

Some of the teaching personnel were acquainted with the encyclopædic American textbooks of biochemistry, many were not. Despite their generally favourable impressions, few thought that students should acquire any of these books The opinion was expressed that they are too detailed, high-powered, and expensive The most telling argument was that "the students won't read them" The texts were in fact considered equivalent to works of reference, suitable for preparation of lectures by staff

TUTORIALS

About half of the schools scheduled tutorials Unless written papers were demanded, few students prepared for these conferences Attendance was inclined to fall off gradually as the term advanced, except at tutorials supervised by the professor The London student, like his American counterpart, is nobody's fool, he knows who grades the final examination

PRACTICAL WORK

London medical students, relatively deficient in science background, lack appreciation of quantitation Perhaps that is why their practical work is geared mainly to qualitative examination of biological materials The student is deluged with qualitative tests, in which he has little interest, the importance of which is not clear to him, and which he usually does in a slipshod fashion Students approach practical work as a chore to be muddled through, and this they do with remarkably good humour and grace Practical work is seldom prepared for in advance "Cooking" is the order of the day except for one session—the practical examination of the 2nd M B—where the students work industriously and intensively, the contrast between examination and daily laboratory work is startling

Some experiments demand a quantitative approach, but the opportunity to emphasise the meaning of significant figures, the value of at least duplicate determinations and concepts of precision and accuracy is seldom fully seized. As medicine progresses towards its status as a true science, requirements for more exact measurement will also increase. Emphasis in practicals may well be placed on quantitative procedures, the results of which lend themselves to a discussion of biological changes from a quantitative as well as a qualitative standpoint.

It is also valuable for future physicians to study the biology of the whole mammal whenever possible This recommendation was capable of engendering fierce controversy among both students and staff The counter argument usually conceded the educational benefits, but moral objections were raised against use of small mammals (mice, rats, guineapigs, rabbits) for student practical work—even though the only operative procedures suggested on the unanesthetised animal were subcutaneous injections and bleeding from tail or ear veins Where such objections prevail—and perhaps in any case—the medical student is himself the best experimental subject A considerable number of practical experiments in the biochemistry laboratory employing man are feasible, and indeed desirable Curiously enough, few people objected to this they simply shuddered at the imagined consequences

Many of these desiderata may be combined in fewer but *better* experiments by students Some schools included a fair sprinkling of practical exercises of this type The list could be profitably expanded [5]

Some instructors fraternise with students, but only a few try to discuss the work in progress during practicals, the general rule seems to be to let the student alone—a practice which the student heartily favours Indeed, students are likely to be shocked or pained if pointed questions about practical procedure or theory are directed at them Thus the opportunity to use some of the practical time for intimate teaching is little grasped Rather, the student races to finish his quota of experiments, and interruptions are unwelcome Tradition favours the students' point of view

Practical data are treated by the schools in various ways At many schools students check out at the end of a period, the check-out consists of a few moments devoted to inspection of each student's data by an instructor and a question or two, after which the student signs the attendance sheet Also, and depending upon the nature of the data, individual results may be tabulated upon the blackboard. These may form the basis for a short class discussion by the instructor either at the end of the day or at the beginning of the following period Students may also be instructed to copy the tabulated class data and to draw their own conclusions One school utilised tutorials for discussion of practical results

[3] Report on Undergraduate Medical Education in Great Britain and Northern Ireland (August, 1957) Part III The Preclinical Curriculum P 17 (table II)

[4] First Teaching Institute the Teaching of Physiology Biochemistry and Pharmacology *J med Educ* 1954, 29, 114 (table 10c)

[5] *ibid* p 115 (table 10d, special experiments)

The individual though necessarily brief check-out has merit, but it should be possible to derive greater benefit from the many long hours spent in practical work. If the significance of this work is not brought home to the student within a reasonable time, these hours are essentially wasted. With other irons in the fire, he is unlikely himself to draw full and correct conclusions from practical work. When the subject is fresh, an hour or so at the end of a practical may be profitably spent discussing class results Individual failure to obtain correct results, errors, and frequency distributions clearly emerge when all class results are compared. Students may thus get the benefit of the work performed by the entire class At least one school has started exactly such a system

" Cooking " should certainly be abolished. There is an understandable reluctance to move against this widespread practice by harassing students with counterparts of anatomy vivas Yet to start practical work without the foggiest notion of the scheduled experiments and their implications is a travesty of laboratory work it is a serious waste of the time alike of student and staff Perhaps better utilisation of practical time can be achieved by having individual teachers spend ten minutes or so with each student every other practical day, during regular practical hours Informal ungraded oral questions on the significance of experiments in progress may be the keynote of these brief discussions A few sessions will readily convince students that it is advisable to prepare for practical work Such intimate teaching may be continued throughout the year and thus afford an opportunity for the students to advance their own questions without inhibition. Each student may be helped to appreciate the state of his knowledge The sessions may also be useful in evaluating students, and the instructor's impressions should be considered in the final student grade

EXAMINATION AND EXAMINATION SYSTEM

Although the all-important 2nd M B in biochemistry is comprehensive in scope it is not without shortcomings Students enjoy wide latitude in their choice of questions, enabling them to get by with very incomplete demonstration of the breadth of their knowledge The questions themselves tend to place a premium on cramming, for what is demanded, more than anything else, is simple recall of lectures, rather than utilisation of knowledge This is not the case with the practical examination

Up to 40% of the marks may be earned by selecting questions on material commonly covered in introductory organic chemistry Despite convenience and tradition, it does seem out of place to ask students, who are ready to start clinical work, how to distinguish primary from secondary and tertiary amines The medical student's memory burden is sufficiently heavy without adding organic straw at the wrong time This point has been made before

The practical examination of the 2nd M B achieves several desirable ends It provides incentive to carry out the assigned experiments during the course It confronts students with problems of logic, makes them organise their biochemical knowledge, and tests their ability to solve scientific problems with mind and hand In fact it is the prototype of what the written theory paper of the 2nd M B *should be* But the proportion of the final student grade in biochemistry given for this single laboratory examination ($^1/_3$) seems somewhat excessive.

Slight adjustment of total biochemistry marks, reflecting the student's performance in trial examinations, may be made if the 2nd M B examination result is borderline There is also more than a hint that a few schools will display a positive bias in these cases if overall weekly laboratory performance has been satisfactory

Theoretically, a student may fail biochemistry proper and still earn a pass in physiology Such cases are said to be rare If the failure is flagrant, the professor of biochemistry has the option of insisting upon student repetition of the entire 2nd M.B examination.

It was wonderfully refreshing to find an examination system as yet uncontaminated by the injudicious use of the so-called objective or short-answer question, an abomination of American education wherein the written equivalent of a grunt serves to gain or lose marks

TEACHERS AND EXAMINERS

The examination system points up a marked difference, not apparent to superficial observation, in the role of the London compared with the United States teacher In the United States the teacher also examines He may be, and should be, somewhat uneasy in his dual role, to a certain extent, the student's examination grade reflects the instructor's success or failure, since lecture notes are frequently regurgitated at examination, with only slight alterations, and the teacher can hardly criticise or fail himself In the United States the preclinical medical student is self-tyrannised by the fear of failing if he by word or act creates an unfavourable impression upon his teachers It does not matter that the basis for this fear is largely illusory Aware that he is under the continual scrutiny of people who one day will be called to sit in judgment, the student is inclined to be distrustful and reserved in his dealings with teachers

The external examiner system avoids such a relationship at the university level and at the same time ensures fairness and uniform standards Under this system the internal staff are teachers, but with the exception of the professor, they do not examine Students are more likely to respect and trust their advisers, rather than grimly contemplate a future game of wits (examination) in which the stakes will be exceedingly high and one-sided The contrast between the relaxed London medical student compared with the tense and over-anxious American student has already been mentioned

The disadvantages of the external examiner system are that the instructors who do most of the teaching, and who are best able to assess students, have little or nothing to say about student grades Also the imposition of uniformity acts as a brake against desirable as well as undesirable innovations in fashioning examinations A professor who wished to drop organic questions from the 2nd M B examination complained that he was prevented from doing so by the external examiner Some modification of the disadvantages may be sought, but admittedly it is difficult to reconcile the desirability of having an instructor function only as a coach and at the same time grant him a voice in awarding final marks

INTERDEPARTMENTAL CORRELATION

Whereas intradepartmental correlation left nothing to be desired (the result perhaps of daily tea, wherein departmental, college, national, and international problems are solved), over half the schools had no interdepartmental correlation plan of any kind Informal arrangements settling the sequence of common topics (i e., respiration, digestion) among departments were considered examples of correlation Where any measure of correlation was observed it was between the departments of physiology and biochemistry, seldom with anatomy. One school, an outstanding exception, integrated biochemistry with all the basic sciences and (even) with clinical subjects.

For the most part, there is little social or academic contact or mixing between junior personnel of biochemistry and the medical staff. This represents a real loss of opportunity for correlation, self-education, and exchange of ideas.

That British medical educators are well aware of the desirability of interdepartmental correlation is evident from the recommendations of the General Medical Council. "Every effort should be made to secure close correlation in the teaching of anatomy, physiology and biochemistry and to stress, wherever opportune the importance of these subjects in their clinical application."[2] The correlation plan of the school cited above could well serve as a model for others anxious to gain the advantage of integration of preclinical subjects. Since there is no distinct division between the biology of the normal and the abnormal, opportunities for the basic-science teacher such as attendance and participation in the London equivalent of clinical-pathological conferences, grand rounds medical conferences, and serving as consultants in cases of metabolic disease should prove stimulating and at the same time furnish a basis for motivating students.

COMPARISON

I am guilty of generalisations, and generalisations, like rules of grammar, are proved by their exceptions. Not all London students were indifferent to biochemistry. Indeed the top students somehow managed to regulate their interests and study time so that the physiological sciences were not altogether slighted. These same students tried to keep up with all their studies. They were motivated not by fear but by intellectual curiosity. It was particularly gratifying to work with such students; they represent the best of both educational systems.

In my opinion the United States has clear advantages in that the importance of biochemistry for medical studies is recognised by clinicians and students. American students are also older, better prepared in science, less casual, more industrious at the preclinical level, and in their pursuit of knowledge, harder to discourage.

Despite these advantages the success of instruction in biochemistry at home leaves no room for complacency. A poll of various groups of physicians in the United States revealed that, whereas they thought that a "good knowledge of biochemistry was important to the good practice of medicine" their preclinical biochemistry course only very indifferently helped them in their practice of medicine. Despite the unanimous respect and emphasis accorded to biochemistry in the United States, it is far from being the handmaiden of medicine.[6]

I wish to thank the many colleagues who have graciously commented upon certain sections of the manuscript. Disagreement with many points was evident and not unexpected. All opinions and interpretations are entirely my responsibility.

Points of View

CORPORAL PUNISHMENT

J. A. WAYCOTT
M.B. Cantab., M.R.C.P., D.C.H.
BARRISTER-AT-LAW

> "I can imagine nothing more repugnant to the most elementary principles of justice and common sense than to say that, because a man has committed a savage offence, those whose duty it is to enforce respect for the law should begin that man's punishment with correspondingly savage treatment."

THESE words were spoken by Lord Oxford sixty years ago. The present agitation for the restoration of corporal punishment is a sad commentary on 20th-century progress. Based as it is on fear and ignorance, it takes little account of the hard fact that all the available evidence is firmly against the view that the cat or birch are effective instruments of penal reform.

Knowledge of violently antisocial persons has increased considerably in recent years. As our ideas of criminal responsibility alter, so it becomes necessary to make fundamental changes in the methods of dealing with some of those convicted of serious crime. Also it is becoming easier to assess the results of various penal methods and to compare their effectiveness as means of protecting the public interest. From this knowledge has emerged in rather stark outline a fact that is exceedingly inconvenient. "To make the punishment fit the crime" is no longer a rational object. It is becoming increasingly obvious that often we must make the punishment fit the criminal. In the present state of public understanding this must give rise to considerable anxiety. When the figures of those convicted of violent crime are a source of further anxiety it is not surprising that there should be a reaction in the direction of retributive punishments.

A further difficulty arises from the fact that the interests of the offender and of the public are often in conflict. The ancient struggle between reform and deterrence is, to some degree reenacted when the sentence to be imposed on an individual offender is determined. What may be in his best interest may not serve the community best. Statistics must ever remain silent upon one of the most important results of a sentence—namely, the effect it has upon potential imitators. Those who commit the same offence a second or third time, and others who copy because they think they can get away with it, all come within the statistical net. But we know nothing of those who might have committed certain offences but for the exemplary punishment of their acquaintances. Notting Hill comes to mind in this connection. In considering the arguments relating to corporal punishment this difficulty is fundamental. Because of the total absence of evidence, it cannot be weighed nicely. Herein lies one of the sources of the unfortunate differences that have divided honest and sincere advocates of corporal punishment from those who are opposed to it.

MAGISTERIAL OPINION

Of course it is true to say that statistics themselves can accurately reflect the united feelings of judges and magistrates. It is beyond belief that these feelings should have failed to take account of the difficult question of deterrence. At the beginning of the present century there were 3385 birchings ordered by the juvenile courts. By 1936 this had fallen to 166. At this time a Departmental Committee on Corporal Punishment[1] was set up "to consider the question of corporal punishment in the penal systems of England and Wales and of Scotland, to review the law and practice relating to the use of this method of punishment by Juvenile Courts, by other courts and as a penalty for certain offences committed by prisoners, and to report what changes are necessary or desirable."

---

[1] Cmd 5684 H.M. Stationery Office, 1938.

In 1948 the great Criminal Justice Act was passed It is a landmark in our legal history, and among other provisions it gave effect to the committee's recommendations It is therefore worth examining these a little more closely

The dramatic decline in the number of birchings was explicable only on the grounds that the majority of juvenile courts had entirely abandoned this method because they found in practice that it was ineffective as a means of treating young offenders Neither could it be shown to have any deterrent quality The busier and more experienced courts had given up corporal punishment altogether The only courts still using it were "in country districts or in the smaller towns" The juvenile courts in London and in many of the larger towns had not made any use of their powers to order corporal punishment "in recent years" These facts become extremely interesting when considered in relation to the present feeling among some magistrates for a return to corporal punishment In January, 1953, a referendum was held among members of the Magistrates Association They were asked to reply to the question "Are you in favour of corporal punishment for crimes of violence?" Those answering "Yes" numbered 4412 and those saying "No" were 1886 The membership at the time was 9451 In *The Magistrate* last October,[2] a doctor who is on the juvenile bench declared that he was "completely convinced that corporal punishment must return", and added that he would "like to commence a movement or even an agitation for its return" In the January issue of this year [3] another correspondent boldly announced his suggestion of "six of the best administered publicly over a form in the Market Place by a Police *Woman* in uniform" (Italics original) Thus the wheel comes the full circle—almost

WHAT IT ENTAILS

It is possible, of course, that not everyone who advocates corporal punishment is fully aware of what it entails If it were to bear even a passing resemblance to the kind of punishment administered by parent or schoolmaster it might have something to commend it But it differs in several important particulars

A youngster dealt with in this way by parent or master receives his punishment shortly after commission of the offence Between punisher and punished there are bonds of respect and affection These continue afterwards in the supervision and care that such persons in authority exercise The punishment itself is not administered in circumstance of extreme humiliation and indignity

When carried out by order of the court things were very different In the first place there was an inevitable delay between the commission of the offence and the passing of the sentence The order of the court was carried out by an officer whose relation with the offender was not likely to be coloured by mutual respect, still less affection It was regarded as essential to identify those individuals who would undoubtedly be harmed or made even more antisocial by such treatment This involved psychological assessment, which was occasionally, and on other grounds, neither necessary nor desirable Practice varied a little from one area to another but in general the description in the Cadogan report [1] was acknowledged to be accurate Those who wish to see these things revived must be quite sure they understand what they are asking for, and for this reason it is worth quoting the words of the report

> "The punishment is usually administered in a cell or private room either within the precincts of the court or at a neighbouring police station The birch is applied across the buttocks on the bare flesh The method most commonly adopted is to bend the boy over a low bench or table His hands, and sometimes his feet also, are held by police officers This is done in order to ensure that he shall not move, for if he moved a stroke of the birch might fall on some more sensitive part of the body This method, though probably the most common, is not universal In some Police Forces one constable takes the boy on his back, drawing the boy's hands down over his shoulders, another constable holds the boy's feet, drawing his legs round the sides of the first constable, the first constable then leans forward, and the birch is applied by a third We have also heard that in one Police Force the custom is for one constable to bend the boy over and hold his head between his knees, while a second officer administers the birch And in one district the boy is strapped to an apparatus similar to the triangle used for corporal punishment in prisons"

For these and other reasons the committee concluded that "as a court penalty, corporal punishment is not an effective method of dealing with young offenders We do not regard it as a suitable penalty for serious cases these require constructive methods of treatment, designed to deal with the causes and conditions underlying the offence, and corporal punishment is essentially non-constructive"

DIAGNOSIS

What then is the alternative? It will be remembered that the Criminal Justice Act made provisions for the setting up of detention centres The white-paper on Penal Practice in a Changing Society [4] proposed an extension of the scope of punitive detention A recent Home Office circular [5] has given the preliminary results of Dr Max Grunhut's research into the effects of detention in detention centres (Dr Grunhut is reader in criminology at the University of Oxford) From this it appears that this method of treatment is suitable for "boys with a more or less substantial criminality not due to deep-rooted personal factors or seriously adverse home conditions, for whom detention is the first experience of any form of institutional treatment" It will be recognised at once that these are just the offenders who might be thought suitable for corporal punishment No-one has ever seriously suggested that psychologically abnormal individuals or those with particularly bad home conditions should be whipped They, and the mentally subnormal and psychopathic offenders, cannot reasonably be subjected to violent punishment in an attempt to get them to mend their ways Those who are most likely to be thought of as candidates for birching are the very individuals for whom the detention centre is most effective A comparison of the results of detention centre and birching leaves little room for doubt that the former is preferable

The first need, in dealing constructively with violent offenders is accurate diagnosis As a Medical Correspondent in *The Times* [6] has pointed out, there are several groups into which they can be fitted even in the present state of knowledge The proper treatment of them depends to some extent upon the category in which they are placed Some will doubtless have to be dealt with by removing them from society for a prolonged period, perhaps indefinitely Provisions contained in the Mental Health Act, soon to become law, will have an important influence The development of units for the treatment of psychopaths, on the lines of the one at the Belmont

Hospital, may define some of the limits in this exceptionally difficult field The probation system will be closely involved with a certain number

Legislative reforms must have a considerable public opinion behind them Unhappily it is also true that general agitation has, on occasions in the past, been the mainspring of retrograde and panic measures To bring back corporal punishment now, despite all the evidence we have, would be to acknowledge that, in some cases at least, motives of revenge must be given priority It is inconceivable that this could serve the interests of the country

AN EASIER ALPHABET ?

S L PUGMIRE
L.R.C.P I, D.P M

SENIOR HOSPITAL MEDICAL OFFICER, WHITTINGHAM HOSPITAL, PRESTON

THE competition for a phonetic alphabet called for in George Bernard Shaw's will brought almost 500 entries, but the panel of judges felt that none merited final adoption My own entry was one of four chosen for further consideration It is based on the principles of information theory, and uses six binary units of information for each letter

I first became interested in this approach to problems of communication while doing research at Rampton State Hospital Some patients had had 14 years' tuition since leaving school and still could neither read nor write The high correlation between antisocial conduct and illiteracy is well known and its cause not hard to find, for our modern society is cruel to the illiterate, especially the child Whatever the cause of his handicap (which may be a specific disability), he is liable to hear himself described as lazy, stupid, subnormal, defective, or feebleminded He is continually reminded of his disability, often blamed, and all too often ridiculed If a few show dislike for their literate neighbours and develop an aggressive reaction toward society, this is not hard to understand What *is* difficult to understand is why people who can think and transmit their thoughts easily in speech are unable to transmit the same messages in writing

I decided to assess the difference in irrelevant information content of the spoken and written language.

Spoken

The ten commonest words (*the, of, and, to, a, in, that, it, is,* and *I*) cover about a quarter of the words in everyday use I examined them to see how far they could be shortened before they lost their identity In full they total 19 sounds and when reduced to (*the, o, a, t, a, i, tha, it, is, I*) only 13 These 13 are essential to identity and 6 are irrelevant, giving about 46% redundancy As these common words seemed shorter than the average, I repeated the exercise with 75% of words in general use starting with the letter A Their approximate frequency per 1000 words is given in parentheses *and* (32), *a* (21), *as* (8), *at* (6), *are* (5), *all* (4), *an* (3), *any* (2), *about* (1), *after* (1), *am* (0 7) They total 26 sounds of which 17 are essential to identity and 9 irrelevant, giving a redundancy of 53%

Written

In the written language 26 letters inadequately cover 40 phonemes (vowel or consonant sounds) Each letter has at least four forms—written and printed, capital and small There is much redundancy in spelling For instance, the long and short sounds *i* each has 20 modes of formation, while the *sh* sound has at least 17

Lastly, many letters contain others within themselves, which is a form of redundancy Thus one does not know whether N or M is being written until the third curve is reached

There is thus much more redundancy in written than in spoken language (about fifty times as much), and this may well be a cause of illiteracy

To confirm this I asked groups of patients to sort packs of cards, say black and white, from random order into two piles—i e, for one unit of information Then for two or three units of information into respectively four and eight piles Cards were identified by distinctive colours or shapes or sizes or combinations of these Information was always handled at a uniform rate as in a binary digital computor, regardless of the form in which it was presented

Some intelligent yet illiterate patients showed an interesting disorder When asked to sort cards into piles of characteristic shapes and colours—say red squares, red triangles, blue squares, and blue triangles—they proceeded at a normal speed, but when asked to disregard the colours and sort only by shape—say, squares and triangles—they could not do the task. They continued as before, sorting into four piles using all information available and could not separate the message (the shapes) from the irrelevant information (the colours) More complex tests confirmed that their brains were functioning like a radio set with no tuning device When one station only was on the air, the radio worked perfectly, but when two stations came on together the set picked up both messages at once and was unable to suppress one message while receiving the other

This finding suggested that for patients of this type a new alphabet should carry no unnecessary information An alphabet in which each letter carried 6 (and only 6) units of information (the minimum possible for 40 letters) would prove most satisfactory To reduce phonemes to 40, minor differences in vowel sounds (as in *but* and *burr*, *bat* and *bare*, *feud* and *futility*, *art* and *artistic*) had to be ignored

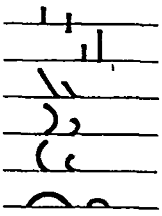
SOME PRINCIPLES AND THEIR APPLICATION

Before beginning to design a simplified alphabet I decided that it must meet the following needs

1 Extreme simplicity
2 Mathematical utility
3 High writing speed
4 Economy in space, paper, and ink.
5 Suitability for typing
6 High reading speed.
7 Adaptability for use in other languages.
8 Accurate transcription of defective script.
9 Letter forms suited to hand movements
10 Suitability for mechanical reading

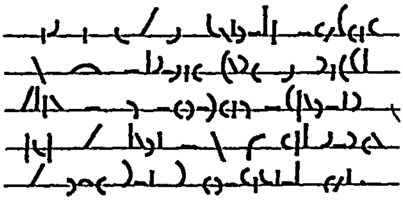
I took a short straight vertical line, as the clearest and most compact letter to write, and added information unit by unit

1st unit —It can be written on or through the line
2nd unit —It can be short or long
3rd unit —It can be inclined to the right or left
4th unit —It can be made concave to the left
5th unit —It can be made concave to the right
6th unit —It can be inclined 90° or not



The later units tended to be less compact and slower to write, so the commonest sounds were attached to the simplest letters They could be joined or not as desired, but, to prevent possible confusion, junctional lines were always written upwards and letters downwards Straight lines were vowels and bent ones consonants, short lines were short vowels, longer lines long vowels

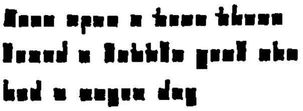
Such simple rules were not only easy to learn but made for clarity even when the writing was poor To emphasise the clear space between words, letters that usually began a word had their cavity to the right and terminal letters to the left Writing speed was further increased by giving each letter a new name The name was the most common word containing the sound the letter signified The letter written alone was read as its name Thus the whole word " eye " could, with saving of time be written " I " The appearance of the alphabet can be judged from this specimen



If it is to be generally adopted
a new alphabet must be simple
clear and of attractive appearance
easy to learn and a great deal faster
to write than the traditional one

SOME DEFECTS

As this alphabet was designed for patients with mental disorders it is not ideal for normal people Perhaps its most serious faults are that letters cannot be identified in isolation and reading speed is lower than is theoretically possible To correct the former it is necessary to add information to each letter which must seriously reduce the writing speed Raising the reading speed is equally baffling because people read by totally different processes Some slow readers sound out the letters, *c-a-t*, while fast readers often identify a whole group of words by their contour This method can be effectively demonstrated by trying to read the story of the little girl and her magic dog printed in this form



Once upon a time there
lived a little girl who
had a magic dog

Letters of different lengths provide good contour effects but are often slow to write The ideal probably lies between 3 or 4 lengths which respectively provide 6 and 10 alternative contours Any final alphabet will result from weighing the advantages against the disadvantages of each change in letter form

The designers of the four alphabets which were commended in the competition have been asked to cooperate in an attempt to produce a final " Shaw Alphabet " free from major defects Whatever the result, it can only be an improvement on our present orthographic system Bernard Shaw must have longed for a phonetic script when writing Miss Dolittle's part in *Pygmalion*, as she slowly changed her accents from that of one section of British society to another When asked about the subject he usually emphasised the saving in money, paper, and ink Books could be a third the size and half the price Children would have no spellings to learn, could write faster and read fluently at a much earlier age The annual saving, he once estimated, would equal the cost of the 1914–18 war Perhaps he thought financial advantages were the only ones that would interest us, for he once wrote "England knows nothing of phonetics, hates education but will do anything for money "

Conference

CORTICOTROPHIN

At the University of Sheffield on Jan 7 and 8, 30 research-workers and clinicians, from several disciplines, met to discuss the adrenocorticotrophic hormone There follows an abstract of the proceedings

Structure and Assay of Corticotrophins

Dr H B F Dixon (Cambridge) described the structure of corticotrophins and their relation to the melanophore stimulating hormones (M S H) Only the most abundant form of corticotrophin that can be extracted from pituitaries has been studied in any detail It is a polypeptide consisting of a chain of 39 aminoacids the sequence of which is known for the bovine form It has a sequence of 9 aminoacids in common with M S H , which may explain the mild M S H activity of corticotrophin Dr Dixon outlined the little that was known relating their structures to their functions, and speculated that M S H must have some function in mammals, otherwise the physiologically active mutant forms would not have survived

In the discussion it was pointed out that there was no agreed nomenclature for corticotrophins and that recommendations were at present being considered by the International Pharmacopeial Commission It was thought that the corticotrophin preparations now available for clinical use contained approximately 50% corticotrophin A and other unknown substances, including protein, but very little M S H activity

Dr M Stack-Dunne (Medical Research Council, Hampstead) discussed the biological assay of corticotrophin Measurement of adrenal ascorbic-acid depletion after subcutaneous injection of corticotrophin in hypophysectomised rats was the only practical and reliable means of assaying corticotrophin for *clinical* use The assay of corticosteroid synthesis in adrenal slices (Saffran and Schally) had the same limitations as the intravenous Sayers assay (adrenal ascorbic-acid depletion) The present 2nd international standard was not suitable for comparison with present-day purified corticotrophin Until the 3rd standard became available each manufacturer was using an approved " house standard " Dr Stack-Dunne said he would be happier about the uniformity of potency of corticotrophins for clinical use when these standards were replaced by a new (3rd) international standard He made a plea that users of corticotrophin inform him at once if they suspect that any batch of corticotrophin is not up to expected strength He pointed out that it had been learnt recently, and was not generally known, that gelatin preparations should be kept at or below 50°F

Dr W J Tindall said that *zinc* preparations must *not* be refrigerated Dr H F West (Sheffield) spoke of the assay of total 17-hydroxycorticosteroids (17(OH)C S) in urine for measuring the effectiveness of corticotrophin therapy If the effectiveness depended upon the adrenal output of cortisol then the assay was sufficiently accurate and an indispensable guide—with two reservations (1) that no condition existed in which 11 or 21 hydroxylation of the corticosteroid molecule was defective (e g , the adrenogenital syndromes or the administration of substances such as SU 4885), and (2) that there may be states in which the proportion of cortisol metabolised 'to 17(OH)C S was abnormal Dr P S Davis (West London Hospital) produced evidence suggesting that such an abnormality was seen sometimes in rheumatoid arthritis If the effectiveness of corticotrophin therapy depended on the concentration of diffusible cortisol in the blood, Dr West suggested that the measurement of free cortisol in the urine might prove a more reliable guide than the assay for 17(OH)C S

Dr J K Norymberski (Sheffield) said that using the published method for the estimation of total 17(OH)C.S a figure of 2 mg or less was meaningless Dr S Shuster (Cardiff) had found a low excretion of 17(OH)C.S in patients with wasting from chronic diseases, which was in keeping with their addisonian-like appearance, but their blood-levels of 17(OH)C.S were either normal or raised He wondered whether they had the altered metabolism of cortisol that is seen during pregnancy Dr C. L COPE (Hammersmith) had found that the adrenal output of cortisol, measured isotopically, confirmed West's assumption that the 17(OH)C.S assay was a reliable guide to cortisol production—but *only* when the turnover was large At physiological levels his figures and those for the 17(OH)C.S excretion did not correlate

Corticotrophin and Aldosterone

Dr BERTHA SINGER (Sheffield) discussed the possible relation of corticotrophin to aldosterone secretion She described the effects on adrenal aldosterone secretion in rats subjected to various experimental procedures and emphasised the difficulties encountered in their interpretation. She favoured the view that when corticotrophin caused an increased secretion of aldosterone, as during salt restriction, the effect was not a direct one on the adrenal glomerulosa zone. She also favoured the hypothesis that the delta-1 corticotrophin fraction of Bell stimulated aldosterone secretion because it was contaminated with a diencephalic or pineal hormone that Farrell had named " glomerulotrophin " There was general agreement with these views and much speculation as to why corticotrophin did not stimulate aldosterone secretion. Current theories of the biosynthesis of corticosteroids suggest that it should A possible explanation suggested by Dr J F TAIT (Worcester Foundation) was that the glomerulosa zone did not bind corticotrophins as the reticularis and fasciculata zones did. Dr STACK-DUNNE maintained that corticotrophin did affect the glomerulosa zone since he and Cater had found a fall in the mitotic activity after hypophysectomy that could be restored by corticotrophin administration.

Dr E Ross (University College Hospital) found a brisk increase in aldosterone excretion following salt deprivation in the recently hypophysectomised patient but little response in the patient with hypopituitarism of long standing The part that growth hormone might play in these circumstances was discussed.

Dr STACK-DUNNE had not found growth hormone (bovine) to affect the rat adrenal glomerulosa zone, but Dr SINGER had some years ago found an increased secretion of aldosterone after growth hormone and Dr Venning had recently confirmed this with improved assay techniques

Dr J G PHILLIPS spoke of the marked adrenal activity in the salmon during its run from the sea to the freshwater spawning grounds, and mentioned the fact that it has no separate glomerulosa zone for aldosterone-secreting cells

Effects of Corticotrophin on Adrenal Cortex

Prof T SYMINGTON (Glasgow) and Dr J K GRANT (Edinburgh) described work, done in collaboration, on the effects of corticotrophin stimulation on the histological appearances, the enzyme activities, and the steroid biosynthesis of the adrenal cortex in vivo and in vitro The work on the human adrenal in vivo was done in collaboration with Mr A P M FORREST (Glasgow)

Professor SYMINGTON said that after stress or corticotrophin therapy the lipid-laden cells of the fasciculata zone changed to cells packed with mitochondria rich in enzymes of the Kreb's cycle. R.N.A. became abundant in the cytoplasm and both zones looked alike These changes were associated with an increased responsiveness to corticotrophin and a marked increase of hydrocortisone secretion relative to corticosterone. The adrenal in this state was " primed "

Dr GRANT critically reviewed the theories so far put forward on the site of action of corticotrophin, and then described some of his own studies on the action of corticotrophins on the enzymes of the adrenal cortex in man. He had found that, in vivo, corticotrophin increased the 11-beta-hydroxylase activity of the mitochondria of the fasciculata and reticularis cells and the 17-and 21-hydroxylase activity of their cytoplasm. Hydrocortisone secretion was increased markedly and corticosterone secretion increased little, or even fell. He thought that the 11 and 17 hydroxylations were increased relative to the 21 and wondered how this could be if corticotrophin produced its effect by making reduced triphosphopyridine nucleotide (T.P.N.H.) available, since all three systems were activated by T.P.N.H

The meeting discussed whether there was a factor that " primes " adrenals, as distinct from producing steroid synthesis The adrenals of Cushing's syndrome patients were considered to be so primed Dr BERYL DAVIES (Imperial Cancer Research Fund Laboratories) said that she had found the blood concentration of corticotrophin in 2 such patients to be 2 to 3 times the normal level (0 8 milli-units per 100 ml.) The significance of the loss of lipid during stimulation of the adrenal cortex was discussed. In vitro the lipid-laden adrenal slice can produce more steroid than the lipid-depleted slice, but it was thought that this did not mean that the lipid-depleted adrenal in vivo was less efficient, or exhausted, since it would have substrate for synthesis continually arriving in the bloodstream. Dr GRANT pointed out that of the many mammals studied the ruminants all had adrenals made up of compact cells (except the golden hamster) whereas all other mammals studied had adrenals packed with lipid-laden cells—in the resting state No explanation for this marked difference was forthcoming

Resistance to Corticotrophin

Dr WEST described studies on the resistance to exogenous (intramuscular) corticotrophin therapy, acquired by some patients, which necessitated a manyfold increase in dose in order to maintain the same clinical effects and excretion daily of 17(OH)C.S in the urine. His evidence suggested that where resistance developed to high doses the cause was likely to be antibody formation (as in some cases of insulin resistance), but where resistance was mild it might be interpreted as due to variation in the normal corticotrophin degradation process, about which nothing was known. In one patient marked resistance developed, even to a highly purified porcine corticotrophin A1 He thought that their failure so far to demonstrate serum-antibodies to purified corticotrophin was due to the technical difficulties of labelling corticotrophin with ^{131}I The discussion raised the following points resistance was not confined to patients with rheumatic diseases, the incidence of acquired resistance developing over 6–12 months was approximately 1 in 6, changing the site of injection did not affect the resistance. One of the difficulties encountered in studying the resistance was the fact that a sufficiently raised level of circulating cortisol would overcome the resistance.

Corticotrophin in Diagnosis

Prof G M. WILSON (Sheffield) had found corticotrophin of particular value in excluding Addison's disease in patients who had become cachectic from an alimentary disorder In his experience corticotrophin tests after prolonged exogenous corticosteroid therapy revealed a great variability in adrenocortical responsiveness which he was at a loss to explain.

Dr K. FOTHERBY (Edinburgh) said that in testing adrenal function we should not forget that in urine there are metabolites of adrenal origin other than the 17(OH)C.S —dehydroepiandrosterone and pregnanediol, for instance Dr WEST spoke of the unexplained patient-to-patient differences in the ketosteroid/17-ketogenic-steroid (17-K.S /17-K.G.S) ratio during corticotrophin therapy Dr V H T JAMES said that at St. Mary's Hospital a number of hirsute women had been seen whose 17-K.S excretion rose excessively in relation to the 17-K.G.S rise during corticotrophin tests The 17-K.S fraction responsible for the rise was not always the same The substance SU4885 was discussed. Dr GRANT had found that it arrested 11-beta-hydroxylation in the adrenal mitochondria but that it did not adversely affect liver mitochondria.

Treatment of Pulmonary Tuberculosis and Rheumatoid Arthritis

Dr L E **HOUGHTON** (Harefield) had used high initial doses of corticosteroids or corticotrophin to suppress the tissue response to the infection and to suppress any hypersensitivity reaction to streptomycin or P A S Both short-term and long-term (3-8 years) effects were excellent Guineapigs given cortisone during B C G immunisation developed a better protection against live tubercle bacilli than those given B C G alone He thought this was due to the cortisone prolonging the antigenic stimulus and not adversely affecting the immunity response

Dr **DAVIS** compared long-term corticotrophin and oral corticosteroid therapy in the treatment of rheumatoid arthritis From a comparison of objective data corticotrophin was found to be superior to cortisone and at least as effective as prednisolone The data from serial radiographs were the most impressive Withdrawal of corticotrophin was less difficult than the withdrawal of oral corticosteroids Of side-effects less peptic ulceration was associated with corticotrophin but more hypertension and androgenic effects

Differences between Corticosteroid and Corticotrophin Therapy

Dr **WEST** emphasised the chief differences, especially the fact that corticosteroid therapy suppresses the adrenal androgen whereas corticotrophin increases its secretion He invited explanations of the observation that rheumatoid arthritics soon adapt to cortisone therapy but do not so adapt to corticotrophin therapy One reason why corticotrophin therapy did not induce peptic ulceration (in his patients) was because they did not need to put aspirin into their empty stomachs in order to get going early in the morning He was very impressed by the severity of the bruising seen in rheumatoid patients after some years of exogenous corticosteroid therapy His preliminary findings were that corticotrophin-treated patients were not similarly affected Dr **SHUSTER** said that this bruising or purpura was due to atrophy of collagen, as in senile skin, which allowed the layers to slip one across the other and tear capillaries Corticosteroid treatment also caused a delay in the resolution of the extravasated blood

Dr **COPE** said that among physicians throughout the world there was a feeling that corticotrophin therapy was in some way better than oral corticosteroid therapy He thought that the increased secretion of androgens might be relevant

Dr F **PAULSEN** (Malmö) referred to a study in Denmark that showed that there was far less osteoporosis with corticotrophin therapy, he thought this, too, might be explained by the androgen factor Dr **JAMES** thought the new anabolic agents might prevent the catabolic effects of corticosteroids Dr **WEST** found, in wasted rheumatoid arthritic patients, that prolonged treatment with the non-virilising nortestosterones caused a striking increase in creatinine excretion but no obvious increase in muscle mass or strength There was considerable discussion of the problem of corticosteroid withdrawal and it was agreed that more knowledge was needed of the means for forestalling and treating iatrogenic pituitary-adrenal insufficiency

Summing up, Prof C H **STUART-HARRIS** drew attention to the value, once more apparent, of discussion between scientists and clinicians working in related fields The integration of biochemical, morphological, and physiological findings had been valuable, and mind sparking on mind had stimulated fresh ideas for the solution of the many unanswered questions He was impressed by the example the rheumatologists set in attempting to measure the effects of corticotrophin from the time of its introduction, and, although it was a side-issue in the conference, he hoped that a plea would go forth from the conference for a concerted effort to solve the problem of pituitary-adrenal unresponsiveness following corticosteroid therapy

A Running Commentary by Peripatetic Correspondents

YOU must be prepared to play an entirely passive role with those who have made illness their business However busy the surgery, at whatever stress to your internal workings, you must first and foremost be pleased to see them You then sit back easily, but not too comfortably, for fear of sleep, and incline the listening ear

> " Yesterday evening I was standing by the back door, just coming back from the toilet as a matter of fact, they are terribly old houses, and time and time again we've asked to have one inside, but you might as well ask for the moon Anyway, it suddenly came over me, that awful feeling right here in the middle of my stomach, and it shot straight up, like a flash of lightning, and out of the top of my head Luckily Mr Thompson was in the kitchen at the time and heard me cry out, or I'd have gone down Of course I knew it was my liver again I was trembling for a good hour afterwards Mr Thompson had to get his own supper, I couldn't have faced the smell Mr Thompson, he's not at all well himself, doctor, he said to me, 'Ada,' he said, 'first thing in the morning, you go down to the doctor and get a bottle of your medicine' "

If you tell these patients that there is nothing the matter with them, they will be really hurt, and justifiably so as their symptoms are real enough, and must have a hearing They will take their story elsewhere, and the rest of the family will leave you en bloc, and possibly half the street as well Anyway, on the rare occasion, when mutual confidence has been established, the cause of the neurosis may be suddenly dropped in your lap
